Categorical Data Analysis

1. Introduction

• Methods for response (dependent) variable $Y$ having scale that is a set of categories

• Explanatory variables may be categorical or continuous or both
Example

\( Y = \) vote in election (Democrat, Republican, Independent)

\( x \)'s - income, education, gender, race

Two types of categorical variables

Nominal - unordered categories

Ordinal - ordered categories

Examples

**Ordinal**

patient condition \((\text{excellent, good, fair, poor})\)

government spending \((\text{too high, about right, too low})\)
Nominal

transport to work \( \text{(car, bus, bicycle, walk, ...)} \)

favorite music \( \text{(rock, classical, jazz, country, folk, pop)} \)

We pay special attention to

binary variables \( (success - fail) \)

for which nominal - ordinal distinction unimportant.
The *binomial* distribution (and its *multinomial* distribution generalization) plays the role that the *normal* distribution does for continuous response.

**Binomial Distribution**

- $n$ Bernoulli trials - two possible outcomes for each (success, failure)
- $\pi = P(\text{success}), \ 1 - \pi = P(\text{failure})$ for each trial
- $Y =$ number of successes out of $n$ trials
- Trials are *independent*

$Y$ has *binomial distribution*
\[ P(y) = \frac{n!}{y!(n-y)!} \pi^y (1 - \pi)^{n-y}, \ y = 0, 1, 2, \ldots, n \]

\[ y! = y(y-1)(y-2)\cdots(1) \text{ with } 0! = 1 \text{ (factorial)} \]

\underline{Example: Vote (Democrat, Republican)}

Suppose \( \pi = \text{prob(Democrat)} = 0.50 \).

For random sample size \( n = 3 \), let \( y \) = number of Democratic votes

\[ p(y) = \frac{3!}{y!(3-y)!} \pi^y 5^{3-y} \]

\[ p(0) = \frac{3!}{0!3!} \cdot 5^0 \cdot 5^3 = 5^3 = 0.125 \]

\[ p(1) = \frac{3!}{1!2!} \cdot 5^1 \cdot 5^2 = 3 \cdot 5^3 = 0.375 \]

\[ y \quad P(y) \]

\[ \begin{array}{cc}
0 & 0.125 \\
1 & 0.375 \\
2 & 0.375 \\
3 & 0.152 \\
\hline
& 1.0
\end{array} \]
Note

- $E(Y) = n\pi$
  
  $Var(Y) = n\pi(1 - \pi), \quad \sigma = \sqrt{n\pi(1 - \pi)}$

- $p = \frac{Y}{n} =$ proportion of success  
  (also denoted $\hat{\pi}$)

\[
E(p) = E\left(\frac{Y}{n}\right) = \pi
\]

\[
\sigma\left(\frac{Y}{n}\right) = \sqrt{\frac{\pi(1 - \pi)}{n}}
\]

- When each trial has > 2 possible outcomes, numbers of outcomes in various categories have \textit{multinomial distribution}
Inference for a Proportion

We conduct inferences about parameters using maximum likelihood

**Definition**: The *likelihood function* is the probability of the observed data, expressed as a function of the parameter value.

**Example**: Binomial, $n = 2$, observe $y = 1$

$$p(1) = \frac{2!}{1!1!} \pi^1 (1 - \pi)^1 = 2\pi (1 - \pi)$$

$$= \ell(\pi)$$

the likelihood function defined for $\pi$ between 0 and 1
If \( \pi = 0 \), probability is \( \ell(0) = 0 \) of getting \( y = 1 \)

If \( \pi = 0.5 \), probability is \( \ell(0.5) = 0.5 \) of getting \( y = 1 \)

**Definition** The *maximum likelihood* (ML) estimate is the parameter value at which the likelihood function takes its maximum.

**Example** \( \ell(\pi) = 2\pi(1 - \pi) \) maximized at \( \hat{\pi} = 0.5 \)

i.e., \( y = 1 \) in \( n = 2 \) trials is most likely if \( \pi = 0.5 \).

ML estimate of \( \pi \) is \( \hat{\pi} = 0.50 \).
Note

• For binomial, $\hat{\pi} = \frac{y}{n}$ = proportion of successes.

• If $y_1, y_2, \ldots, y_n$ are independent from normal (or many other distributions, such as Poisson), ML estimate $\hat{\mu} = \bar{y}$.

• In ordinary regression ($Y \sim$ normal) “least squares” estimates are ML.

• For large $n$ for any distribution, ML estimates are optimal (no other estimator has smaller standard error)

• For large $n$, ML estimators have approximate normal sampling distributions (under weak conditions)
ML Inference about Binomial Parameter

\[ \hat{\pi} = p = \frac{y}{n} \]

Recall \( E(p) = \pi, \sigma(p) = \sqrt{\frac{\pi(1-\pi)}{n}} \).

• Note \( \sigma(p) \downarrow \) as \( n \uparrow \), so \( p \to \pi \) (law of large numbers, true in general for ML)

• \( p \) is a sample mean for (0,1) data, so by Central Limit Theorem, sampling distribution of \( p \) is approximately normal for large \( n \) (True in general for ML)
Significance Test for binomial parameter

\[ H_o : \pi = \pi_o \]

\[ H_a : \pi \neq \pi_o \quad \text{(or 1-sided)} \]

Test statistic

\[ z = \frac{p - \pi_o}{\sigma(p)} = \frac{p - \pi_o}{\sqrt{\frac{\pi_o(1-\pi_o)}{n}}} \]

has large-sample standard normal (denoted \( N(0, 1) \)) null distribution. (Note use null SE for test)

\( p \)-value = two-tail probability of results at least as extreme as observed (if null were true)
Confidence interval (CI) for binomial parameter

Definition Wald CI for a parameter \( \theta \) is
\[
\hat{\theta} \pm z_{\frac{\alpha}{2}} (SE)
\]

(e.g., for 95\% confidence, estimate plus and minus 1.96 estimated standard errors, where \( z_{0.025} = 1.96 \))

Example \( \theta = \pi, \quad \hat{\theta} = \hat{\pi} = p \)

\[
\sigma(p) = \sqrt{\frac{\pi(1-\pi)}{n}} \quad \text{estimated by}
\]

\[
SE = \sqrt{\frac{p(1-p)}{n}}
\]

95\% CI is \( p \pm 1.96 \sqrt{\frac{p(1-p)}{n}} \)

Note Wald CI often has poor performance in categorical data analysis unless \( n \) quite large.
Example: Estimate $\pi = \text{population proportion of vegetarians}$

For $n = 20$, we get $y = 0$

$p = \frac{0}{20} = 0.0$

95% CI: $0 \pm 1.96 \sqrt{\frac{0 \times 1}{20}}$

$= 0 \pm 0$,

$= (0, 0)$
• Note what happens with Wald CI for \( \pi \) if \( p = 0 \) or 1

• *Actual* coverage probability much less than 0.95 if \( \pi \) near 0 or 1.

• Wald 95% CI = set of \( \pi_o \) values for which \( p\)-value > .05 in testing

\[
H_o : \pi = \pi_o \quad H_a : \pi \neq \pi_o
\]

using

\[
z = \frac{p - \pi_o}{\sqrt{\frac{p(1-p)}{n}}} \quad \text{(denominator uses estimated SE)}
\]
**Definition**  *Score test, score CI* use null \( SE \)

e.g. Score 95% CI = set of \( \pi_o \) values for which \( p \)-value > 0.05 in testing

\[
H_o : \pi = \pi_o \quad H_a : \pi \neq \pi_o
\]

using

\[
z = \frac{p-\pi_o}{\sqrt{\frac{\pi_o(1-\pi_o)}{n}}} \quad \leftarrow \text{note null } SE \text{ in denominator}
\]

(known, not estimated)
**Example** $\pi =$ probability of being vegetarian

$y = 0, \quad n = 20, \quad p = 0$

What $\pi_o$ satisfies

$$\pm 1.96 = \frac{0 - \pi_o}{\sqrt{\pi_o (1 - \pi_o) / 20}}$$

$$1.96 \sqrt{\frac{\pi_o (1 - \pi_o)}{20}} = |0 - \pi_o|$$

$\pi_o = 0$ is one solution

solve quadratic $\rightarrow \pi_o = .16$ other solution

95% score CI is $(0. \ 0.16)$, more sensible than Wald CI of $(0, 0)$. 
• When solve quadratic, can show midpoint of 95% CI is 

\[
\frac{y + 1.96^2/2}{n + 1.96^2} \approx \frac{y + 2}{n + 4}
\]

• Wald CI \( p \pm 1.96 \sqrt{p(1-p)/n} \) also works well if add 2 successes, add 2 failures before applying (this is the “Agresti-Coull method”)

• For inference about proportions, \textit{score} method tends to perform better than \textit{Wald} method, in terms of having actual error rates closer to the advertised levels.

• Another good test, CI uses the \textit{likelihood function} 

  (e.g. CI = values of \( \pi \) for which \( \ell(\pi) \) close to \( \ell(\hat{\pi}) \) 

  = values of \( \pi_o \) not rejected in “likelihood-ratio test”)

• For small \( n \), inference uses actual binomial sampling dist. of data instead of normal approx. for that dist.
2. **Two-Way Contingency Tables**

Example: Physicians Health Study (5 year)

<table>
<thead>
<tr>
<th>GROUP</th>
<th>HEART ATTACK</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Yes</td>
<td>No</td>
<td>Total</td>
</tr>
<tr>
<td>Placebo</td>
<td>189</td>
<td>10,845</td>
<td>11,034</td>
</tr>
<tr>
<td>Aspirin</td>
<td>104</td>
<td>10,933</td>
<td>11,037</td>
</tr>
</tbody>
</table>

2x2 table

Contingency table - cells contain counts of outcomes. 

$I \times J$ table has $I$ rows, $J$ columns.
A *conditional dist* refers to prob. dist. of $Y$ at fixed level of $x$.

**Example:**

<table>
<thead>
<tr>
<th></th>
<th>$Y$</th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Yes</td>
<td>No</td>
<td>Total</td>
<td></td>
</tr>
<tr>
<td>$X$</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Placebo</td>
<td>.017</td>
<td>.983</td>
<td>1.0</td>
<td></td>
</tr>
<tr>
<td>Aspirin</td>
<td>.009</td>
<td>.991</td>
<td>1.0</td>
<td></td>
</tr>
</tbody>
</table>

Sample conditional dist. for placebo group is

\[
.017 = \frac{189}{11,034}, \quad .983 = \frac{10,845}{11,034}
\]

Natural way to look at data when

$Y = \text{response var.}$

$X = \text{explanatory var.}$
Example: Diagnostic disease tests

$Y =$ outcome of test: $1 =$ positive $2 =$ negative

$X =$ reality: $1 =$ diseased $2 =$ not diseased

<table>
<thead>
<tr>
<th></th>
<th>1</th>
<th>2</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>X</td>
<td>Y</td>
</tr>
<tr>
<td>2</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

sensitivity $= P(Y = 1|X = 1)$

specificity $= P(Y = 2|X = 2)$

If you get positive result, more relevant to you is $P(X = 1|Y = 1)$. This may be low even if sensitivity, specificity high. (See pp. 23-24 of text for example of how this can happen when disease is relatively rare.)
What if $X, Y$ both response var’s?

$\{\pi_{ij}\} = \{P(X = i, Y = j)\}$ form the joint distribution of $X$ and $Y$.

$\begin{array}{ccc}
\pi_{11} & \pi_{12} & \pi_{1+} \\
\pi_{21} & \pi_{22} & \pi_{2+} \\
\pi_{+1} & \pi_{+2} & 1.0 \\
\end{array}$

marginal probabilities

Sample cell counts $\{n_{ij}\}$

cell proportions $\{p_{ij}\}$

$p_{ij} = \frac{n_{ij}}{n}$ with $n = \sum_i \sum_j n_{ij}$
**Definition** X and Y are *statistically independent* if true conditional dist. of Y is identical at each level of x.

\[
\begin{array}{c c}
X & Y \\
0.01 & 0.99 \\
0.01 & 0.99 \\
\end{array}
\]

Then, \( \pi_{ij} = \pi_{i+} \pi_{+j} \) all \( i, j \)

i.e., \( P(X = i, Y = j) = P(X = i)P(Y = j) \), such as

\[
\begin{array}{c c c}
X & Y & \\\n0.28 & 0.42 & 0.7 \\
0.12 & 0.18 & 0.3 \\
0.4 & 0.6 & 1.0 \\
\end{array}
\]
Comparing Proportions in 2x2 Tables

\[
\begin{array}{c|cc}
& Y & \\
X & S & F \\
1 & \pi_1 & 1 - \pi_1 \\
2 & \pi_2 & 1 - \pi_2 \\
\end{array}
\]

Conditional Distributions

\[\hat{\pi}_1 - \hat{\pi}_2 = p_1 - p_2\]

\[
SE(p_1 - p_2) = \sqrt{\frac{p_1(1-p_1)}{n_1} + \frac{p_2(1-p_2)}{n_2}}
\]

Example: \(p_1 = .017, p_2 = .009, p_1 - p_2 = .008\)

\[
SE = \sqrt{\frac{.017 \times .983}{11,034} + \frac{.009 \times .991}{11,037}} = .0015
\]

95% CI for \(\pi_1 - \pi_2\) is \(.008 \pm 1.96(.0015) = (.005, .011)\).

Apparently \(\pi_1 - \pi_2 > 0\) (i.e., \(\pi_1 > \pi_2\)).
Relative Risk $= \frac{\pi_1}{\pi_2}$

Example: Sample $\frac{\hat{p}_1}{\hat{p}_2} = \frac{.017}{.009} = 1.82$

Sample proportion of heart attacks was 82\% higher for placebo group.

Note

• See p. 58 of text for SE formula

• SAS provides CI for $\pi_1/\pi_2$.

Example: 95\% CI is (1.43, 2.31)

• Independence $\iff \frac{\pi_1}{\pi_2} = 1.0.$
Odds Ratio

<table>
<thead>
<tr>
<th>Group</th>
<th>S</th>
<th>F</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>$\pi_1$</td>
<td>$1 - \pi_1$</td>
</tr>
<tr>
<td>2</td>
<td>$\pi_2$</td>
<td>$1 - \pi_2$</td>
</tr>
</tbody>
</table>

The *odds* the response is a *S* instead of an *F* = \(\frac{\text{prob}(S)}{\text{prob}(F)}\)

= \(\frac{\pi_1}{1 - \pi_1}\) in row 1.

= \(\frac{\pi_2}{1 - \pi_2}\) in row 2.

e.g., if odds = 3, *S* three times as likely as *F*.

e.g., if odds = \(\frac{1}{3}\), *F* three times as likely as *S*. 
Odds = 3 ⇒ \( P(S) = \frac{3}{4} \), \( P(F) = \frac{1}{4} \)

\[
P(S) = \frac{\text{odds}}{1 + \text{odds}}
\]

odds = \( \frac{1}{3} \) ⇒ \( P(S) = \frac{1/3}{1+1/3} = \frac{1}{4} \)

**Definition**: Odds Ratio

\[
\theta = \frac{\pi_1/(1 - \pi_1)}{\pi_2/(1 - \pi_2)}
\]
Example

<table>
<thead>
<tr>
<th>Heart Attack</th>
<th>Placebo</th>
<th>Yes</th>
<th>No</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Aspirin</td>
<td>104</td>
<td>10,933</td>
<td>11,037</td>
<td></td>
</tr>
<tr>
<td>Placebo</td>
<td>189</td>
<td>10,845</td>
<td>11,034</td>
<td></td>
</tr>
</tbody>
</table>

Sample Proportions

\[
p_1 \quad 1 - p_1 = \begin{array}{c|c|c}
p_1 & 1 - p_1 & 1.0 \\
0.0171 & 0.9829 & 1.0 \\
\end{array}
\]

\[
p_2 \quad 1 - p_2 = \begin{array}{c|c|c}
p_2 & 1 - p_2 & 1.0 \\
0.0094 & 0.9906 & 1.0 \\
\end{array}
\]

Sample odds =

\[
\frac{0.0171}{0.9829} = \frac{189}{10,845} = 0.0174, \text{ placebo}
\]

\[
= \frac{104}{10,933} = 0.0095, \text{ aspirin}
\]
Sample odds Ratio

$\hat{\theta} = \frac{.0174}{.0095} = 1.83$

The odds of a heart attack for placebo group were 1.83 time odds for aspirin group (i.e., 83% higher)

**Properties of odds ratio**

* Each odds $\geq 0$, and $\theta \geq 0$.

* $\theta = 1$ when $\pi_1 = \pi_2$; i.e., response independent of group

* The farther $\theta$ falls from 1, the stronger the association

(For $Y = $ lung cancer, some studies have $\theta \approx 10$ for $X = $ smoking, $\theta \approx 2$ for $X = $ passive smoking)
- If rows interchanged, or if columns interchanged, $\theta \rightarrow 1/\theta$.

  e.g. $\theta = 3$, $\theta = \frac{1}{3}$ represent same strength of association but in opposite directions.

- For counts

  \[
  \hat{\theta} = \frac{n_{11}/n_{12}}{n_{21}/n_{22}} = \frac{n_{11}n_{22}}{n_{12}n_{21}}
  \]

  = cross-product ratio

  (Yule 1900) (strongly criticized by K. Pearson!)
• Treats $X, Y$ symmetrically

<table>
<thead>
<tr>
<th>Heart Attack</th>
<th>Placebo</th>
<th>Aspirin</th>
</tr>
</thead>
<tbody>
<tr>
<td>Yes</td>
<td></td>
<td></td>
</tr>
<tr>
<td>No</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

$\rightarrow \hat{\theta} = 1.83$

• $\theta = 1 \iff \log \theta = 0$

log odds ratio symmetric about 0

e.g., $\theta = 2 \Rightarrow \log \theta = .7$

$\theta = 1/2 \Rightarrow \log \theta = -.7$

• Sampling dist. of $\hat{\theta}$ skewed to right, $\approx$ normal only for very large $n$.

**Note:** We use “natural logs” ($LN$ on most calculators)

This is the log with base $e = 2.718...$
• Sampling dist. of log $\hat{\theta}$ is closer to normal, so construct CI for log $\theta$ and then exponentiate endpoints to get CI for $\theta$.

Large-sample (asymptotic) standard error of log $\hat{\theta}$ is

$$SE(\log \hat{\theta}) = \sqrt{\frac{1}{n_{11}} + \frac{1}{n_{12}} + \frac{1}{n_{21}} + \frac{1}{n_{22}}}$$

CI for log $\theta$ is

$$\log \hat{\theta} \pm z_{\frac{\alpha}{2}} \times SE(\log \hat{\theta})$$

$(e^L, e^U)$ is CI for $\theta$
Example: \[ \hat{\theta} = \frac{189 \times 10,933}{104 \times 10,845} = 1.83 \]

\[ \log \hat{\theta} = .605 \]

\[ SE(\log \hat{\theta}) = \sqrt{\frac{1}{189} + \frac{1}{10,933} + \frac{1}{104} + \frac{1}{10,845}} = .123 \]

95% CI for \( \log \theta \) is

\[ .605 \pm 1.96(.123) = (.365, .846) \]

95% CI for \( \theta \) is

\[ (e^{.365}, e^{.846}) = (1.44, 2.33) \]

Apparently \( \theta > 1 \)
$e$ denotes *exponential* function

$e^0 = 1$, $e^1 = e = 2.718 \ldots$

$e^{-1} = \frac{1}{e} = .368$

$e^x > 0$ all $x$

exp fn. = antilog for natural log scale $\ln$

$e^0 = 1$ means $\log_e(1) = 0$

$e^1 = 2.718$ \hspace{1cm} $\log_e(2.718) = 1$

$e^{-1} = .368$ \hspace{1cm} $\log_e(.368) = -1$

$\log_e(2) = .693$ means $e^{.693} = 2$
Notes

• $\hat{\theta}$ not midpoint of CI, because of skew

• If any $n_{ij} = 0$, $\hat{\theta} = 0$ or $\infty$, and better estimate and SE results by replacing $\{n_{ij}\}$ by $\{n_{ij} + .5\}$.

• When $\pi_1$ and $\pi_2$ close to 0

$$\theta = \frac{\pi_1/(1 - \pi_1)}{\pi_2/(1 - \pi_2)} \approx \frac{\pi_1}{\pi_2}$$

the relative risk
**Example:** Case-control study in London hospitals (Doll and Hill 1950)

\[ X = \text{smoked } \geq 1 \text{ cigarette per day for at least 1 year?} \]

\[ Y = \text{Lung Cancer} \]

\[
\begin{array}{c|cc}
X & \text{Lung Cancer} & \text{} \\
& \text{Yes} & \text{No} \\
\hline
\text{Yes} & 688 & 650 \\
\text{No} & 21 & 59 \\
\hline
\text{Total} & 709 & 709
\end{array}
\]

Case control studies are “retrospective.” Binomial sampling model applies to \( X \) (sampled within levels of \( Y \)), not to \( Y \).

Cannot estimate \( P(Y = yes|x) \),

or \( \pi_1 - \pi_2 = \\
P(Y = yes|X = yes) - P(Y = yes|X = no) \)

or \( \pi_1/\pi_2 \)
We can estimate $P(X|Y)$, so can estimate $\theta$.

\[
\hat{\theta} = \frac{\hat{P}(X = yes|Y = yes)/\hat{P}(X = no|Y = yes)}{\hat{P}(X = yes|Y = no)/\hat{P}(X = no|Y = no)} \\
= \frac{(688/709)/(21/709)}{(650/709)/(59/709)} \\
= \frac{688 \times 59}{650 \times 21} = 3.0
\]

Odds of lung cancer for smokers were 3.0 times odds for non-smokers.

In fact, if $P(Y = yes|X)$ is near 0, then $\theta \approx \pi_1/\pi_2 =$ rel. risk, and can conclude that prob. of lung cancer is $\approx 3.0$ times as high for smokers as for non-smokers.
Chi - Squared Tests of Independence

</tbody>
</table>

Data from General Social Survey (1991)
$H_0$: $X$ and $Y$ independent

$H_a$: $X$ and $Y$ dependent

$H_0$ means

$$P(X = i, Y = j) = P(X = i)P(Y = j)$$

$$\pi_{ij} = \pi_i\pi_j$$

Expected frequency $\mu_{ij} = n\pi_{ij}$

= mean of dist. of cell count $n_{ij}$

= $n\pi_i\pi_j$ under $H_0$.

ML estimates $\hat{\mu}_{ij} = n\hat{\pi}_i\hat{\pi}_j$

$$= n\left(\frac{n_i}{n}\right)\left(\frac{n_j}{n}\right) = \frac{n_i+n_j}{n}$$

called estimated expected frequencies
Test Statistic

\[ X^2 = \sum_{all \ cells} \frac{(n_{ij} - \hat{\mu}_{ij})^2}{\hat{\mu}_{ij}} \]

called Pearson chi-squared statistic (Karl Pearson, 1900)

\( X^2 \) has large-sample chi-squared dist. with
\( df = (I - 1)(J - 1) \)

\( I \) = number of rows, \( J \) = number of columns

\( P \)-value = \( P(X^2 \geq X^2 \text{ observed}) \)

= right-tail prob.

(Table on p. 343 text)
Example: Job satisfaction and income

\[ X^2 = 11.5 \]

\[ df = (I - 1)(J - 1) = 3 \times 3 = 9 \]

Evidence against \( H_o \) is weak.

Plausible that job satisfaction and income are independent.
Note

- Chi-squared dist. has $\mu = df$, $\sigma = \sqrt{2df}$, more bell-shaped as $df \uparrow$

- Likelihood-ratio test stat.

$$G^2 = 2 \sum n_{ij} \log \left( \frac{n_{ij}}{\hat{\mu}_{ij}} \right)$$

$$= -2 \log \left[ \frac{\text{maximize likelihood when } H_0 \text{ true}}{\text{maximize likelihood generally}} \right]$$

$G^2$ also is approx. $\chi^2$, $df = (I - 1)(J - 1)$. 
Example: $G^2 = 13.47, df = 9, P$-value = .14

• df for $X^2$ test
  = no. parameters in general - no. parameters under $H_o$

Example: Indep. $\pi_{ij} = \pi_i + \pi_j$

$$df = (IJ - 1) - [(I - 1) + (J - 1)]$$

$$\sum \pi_{ij} = 1 \quad \sum \pi_i = 1 \quad \sum \pi_j = 1$$

$$= (I - 1)(J - 1) \leftarrow \text{Fisher 1922 (not Pearson 1900)}$$

• $X^2 = G^2 = 0$ when all $n_{ij} = \hat{\mu}_{ij}$.

• As $n \uparrow$, $X^2 \to \chi^2$ faster than $G^2 \to \chi^2$, usually close if most $\hat{\mu}_{ij} \geq 5$
• These tests treat $X, Y$ as nominal. Reorder rows columns, $X^2, G^2$ unchanged

Sec. 2.5 (we skip) presents ordinal tests. We re-analyze with ordinal model in Ch. 6 (more powerful, much smaller $P$-value).
Standardized (Adjusted) Residuals

\[ r_{ij} = \frac{n_{ij} - \hat{\mu}_{ij}}{\sqrt{\hat{\mu}_{ij}(1-p_i)(1-p_j)}} \]

Under \( H_0: \) indep., \( r_{ij} \approx \) std. normal \( N(0, 1) \)

so \(|r_{ij}| > 2 \) or \( 3 \) represents cell that provides strong evidence against \( H_0 \)

Example: \( n_{44} = 8, \hat{\mu}_{44} = \frac{24 \times 23}{104} = 5.31 \)

\[ r_{44} = \frac{8 - 5.31}{\sqrt{5.31(1 - \frac{24}{104})(1 - \frac{23}{104})}} = 1.51 \]

None of cells show much evidence of association.
Example

<table>

General Social Survey data (variables Sex, Relpersn)

\[ X^2 = 20.6, \ G^2 = 20.7, \ df = 3, \ P\text{-value} = 0.000 \]

- SAS (PROC GENMOD) also provides “Pearson residuals” (label reschi)

\[ e_{ij} = \frac{n_{ij} - \hat{\mu}_{ij}}{\sqrt{\hat{\mu}_{ij}}} \]

which are simpler but less variable than \( N(0, 1) \).

\[ (\sum e_{ij}^2 = X^2) \]

<tr>
<td>(P = .02 P = .01)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>11.76</td>
<td>13.47</td>
<td>9</td>
</tr>
</tbody>
</table>

**Note**

- Job satisfaction appears to depend on whether income > or < $15,000
- $G^2$ exactly partitions, $X^2$ does not
- Text gives guidelines on how to partition so separate components indep., which is needed for $G^2$ to partition exactly.
Small-sample test of indep.

2 x 2 case (Fisher 1935)

<table>
<thead>
<tr>
<th>n_{11}</th>
<th>n_{12}</th>
<th>n_{1+}</th>
</tr>
</thead>
<tbody>
<tr>
<td>n_{21}</td>
<td>n_{22}</td>
<td>n_{2+}</td>
</tr>
<tr>
<td>n_{+1}</td>
<td>n_{+2}</td>
<td>n</td>
</tr>
</tbody>
</table>

Exact null dist. of \{n_{ij}\}, based on fixed row and column totals, is

\[
P(n_{11}) = \frac{\binom{n_{1+}}{n_{11}} \binom{n_{2+}}{n_{+1}-n_{11}}}{\binom{n}{n_{+1}}}
\]

Where \(\binom{a}{b} = \frac{a!}{b!(a-b)!}\)

Hypergeometric dist.
Example  Tea Tasting (Fisher)

<table>
<thead>
<tr>
<th>Poured First</th>
<th>GUESS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Milk</td>
<td>?</td>
</tr>
<tr>
<td>Tea</td>
<td>4</td>
</tr>
</tbody>
</table>

\[n_{11} = 0, 1, 2, 3, \text{ or } 4\]

\[
\begin{array}{ccc}
4 & 0 & 4 \\
0 & 4 & \\
\end{array}
\]

has prob.

\[
P(4) = \frac{\binom{4}{4} \binom{4-4}{8-4}}{\binom{8}{4}} = \frac{4! 4!}{4! 0! 4!} \frac{8!}{4! 4!}
\]

\[= \frac{4! 4!}{8!} = \frac{1}{70} = 0.014\]

\[
P(3) = \frac{\binom{4}{3} \binom{4}{1}}{\binom{8}{4}} = \frac{16}{70} = 0.229\]
For 2 x 2 tables,

\[ H_0: \text{indep} \iff H_o: \theta = 1 \text{ for } \theta = \text{odds ratio} \]

For \( H_o : \theta = 1 \), \( H_a : \theta > 1 \),

\[
P\text{-value} = P(\hat{\theta} \geq \hat{\theta}_{obs})
\]
\[
= .229 + .014 = .243.
\]

Not much evidence against \( H_o \)

Test using hypergeometric called \textit{Fisher’s exact test}.  

\begin{tabular}{|c|c|}
\hline
\( n_{11} \) & \( P(n_{11}) \) \\
\hline
0 & .014 \\
1 & .229 \\
2 & .514 \\
3 & .229 \\
4 & .014 \\
\hline
\end{tabular}
For $H_a : \theta \neq 1$, $P$-value =

two-tail prob. of outcomes no more likely than observed

Example: $P$-value = $P(0) + P(1) + P(3) + P(4) = .486$

Note:
- Fisher’s exact test extends to $I \times J$ tables ($P$-value = .23 for job sat. and income)

- If make conclusion, e.g., rejecting $H_0$ if $p \leq \alpha = .05$, actual $P$ (type I error) < .05 because of discreteness (see text)
### Three - Way Contingency Tables

**Example:** FL death penalty court cases

<table>
<thead>
<tr>
<th>Victim’s Race</th>
<th>Defendant’s Race</th>
<th>Death Penalty</th>
<th>% Yes</th>
</tr>
</thead>
<tbody>
<tr>
<td>White</td>
<td>White</td>
<td>53</td>
<td>414</td>
</tr>
<tr>
<td></td>
<td>Black</td>
<td>11</td>
<td>37</td>
</tr>
<tr>
<td>Black</td>
<td>White</td>
<td>0</td>
<td>16</td>
</tr>
<tr>
<td></td>
<td>Black</td>
<td>4</td>
<td>139</td>
</tr>
</tbody>
</table>

$Y =$ death penalty (response var.)  
$X =$ defendant’s race (explanatory)  
$Z =$ victim’s race (control var.)
<table>
<thead>
<tr>
<th>53</th>
<th>414</th>
</tr>
</thead>
<tbody>
<tr>
<td>11</td>
<td>37</td>
</tr>
<tr>
<td>0</td>
<td>16</td>
</tr>
<tr>
<td>4</td>
<td>139</td>
</tr>
</tbody>
</table>

are partial tables

They control (hold constant) $Z$

The conditional odds ratios are:

$$Z = \text{white} : \hat{\theta}_{XY(1)} = \frac{53 \times 37}{414 \times 11} = .43$$

$$Z = \text{black} : \hat{\theta}_{XY(2)} = 0.00 \quad (.94 \text{ after add .5 to cells})$$

*Controlling* for victim’s race, odds of receiving death penalty were lower for white defendants than black defendants.
Add partial tables $\rightarrow$ XY marginal table

<table>
<thead>
<tr>
<th></th>
<th>Yes</th>
<th>No</th>
</tr>
</thead>
<tbody>
<tr>
<td>W</td>
<td>$n_{11}$</td>
<td>$n_{12}$</td>
</tr>
<tr>
<td>B</td>
<td>$n_{21}$</td>
<td>$n_{22}$</td>
</tr>
</tbody>
</table>

$\hat{\theta}_{XY} = 1.45$

*Ignoring* victim’s race, odds of death penalty *higher* for white defendant’s.

**Simpson’s Paradox:** All partial tables show reverse assoc. from that in marginal table.

*Cause?*

*Moral?* Can be dangerous to “collapse” contingency tables.
Def. $X$ and $Y$ are *conditionally independent given* $Z$, if they are independent in each partial table.

In $2 \times 2 \times K$ table,

$$\theta_{XY(1)} = \cdots = \theta_{XY(K)} = 1.0$$

**Note** Does not imply $X$ and $Y$ indep. in marginal two-way table

<table>
<thead>
<tr>
<th>Clinic</th>
<th>Treatment</th>
<th>Response</th>
<th>$Y$</th>
<th>$\theta$</th>
</tr>
</thead>
<tbody>
<tr>
<td>Z</td>
<td>X</td>

<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>Marginal</td>
<td>A</td>
<td>20</td>
<td>2.0</td>
</tr>
<tr>
<td></td>
<td></td>
<td>B</td>
<td>20</td>
<td>40</td>
</tr>
</tbody>
</table>
3. **Generalized Linear Models**

*Components* of a GLM

1. *Random Component*

   Identify response var. $Y$

   Assume independent observ’s $y_1, \ldots, y_n$ from particular form of dist., such as Poisson or binomial

   Model how $\mu_i = E(Y_i)$ depends on explanatory var’s
2. **Systematic component**

Pick explanatory var’s $x_1, \ldots, x_k$ for *linear predictor*

$$\alpha + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_k x_k$$

3. **Link function**

Model function $g(\mu)$ of $\mu = E(Y)$ using

$$g(\mu) = \alpha + \beta_1 x_1 + \cdots + \beta_k x_k$$

$g$ is the *link function*
Example

- \( \log(\mu) = \alpha + \beta_1 x_1 + \ldots \) uses \( g(\mu) = \log(\mu) \).

*log* link often used for a “count” random component, for which \( \mu > 0 \).

- \( \log\left(\frac{\mu}{1-\mu}\right) = \alpha + \beta_1 x_1 + \ldots \) uses \( g(\mu) = \log\left(\frac{\mu}{1-\mu}\right) \), the *logit* link.

Often used for binomial, with \( \mu = \pi \) between 0 and 1

(*logit* = log of odds)

- \( \mu = \alpha + \beta_1 x_1 + \ldots \) uses \( g(\mu) = \mu \), *identity* link

  e.g., ordinary regression for normal response.
Note:

• A GLM generalizes ordinary regression by

1. permitting $Y$ to have a dist. other than normal

2. permitting modeling of $g(\mu)$ rather than $\mu$.

• The same ML (max. likelihood) fitting procedure applies to all GLMs. This is basis of software such as PROC GENMOD in SAS.

(Nelder and Wedderburn, 1972)
GLMs for Binary Data

Suppose \( Y = 1 \) or \( 0 \)

Let \( P(Y = 1) = \pi \), “Bernoulli trial”

\[
P(Y = 0) = 1 - \pi
\]

This is binomial for \( n = 1 \) trial

\[
E(Y) = \pi
\]

\[
Var(Y) = \pi(1 - \pi)
\]

For explan. var. \( x \), \( \pi = \pi(x) \) varies as \( x \) varies.

Linear probability model \( \pi(x) = \alpha + \beta x \)
This is a GLM for binomial random component and identity link fn.

\[ \text{Var}(Y) = \pi(x)[1 - \pi(x)] \] varies as \( x \) varies, so least squares not optimal.

Use ML to fit this and other GLMs.

ex. \( Y = \) infant sex organ malformation

\( 1 = \) present, \( 0 = \) absent

\( x = \) mother’s alcohol consumption

(average drinks per day)
<table>
<thead>
<tr>
<th>Alcohol Consumption</th>
<th>Malformation</th>
<th>Proportion Present</th>
<th>Present</th>
<th>Absent</th>
<th>Total</th>
<th>Present</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>48</td>
<td>17,066</td>
<td>17,114</td>
<td>.0028</td>
<td></td>
<td></td>
</tr>
<tr>
<td>&lt; 1</td>
<td>38</td>
<td>14,464</td>
<td>14,502</td>
<td>.0026</td>
<td></td>
<td></td>
</tr>
<tr>
<td>1-2</td>
<td>5</td>
<td>788</td>
<td>793</td>
<td>.0063</td>
<td></td>
<td></td>
</tr>
<tr>
<td>3-5</td>
<td>1</td>
<td>126</td>
<td>127</td>
<td>.0079</td>
<td></td>
<td></td>
</tr>
<tr>
<td>$\geq$ 6</td>
<td>1</td>
<td>37</td>
<td>38</td>
<td>.0262</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Using $x$ scores (0, .5, 1.5, 4.0, 7.0), linear prob. model for $\pi = \text{prob. malformation present}$ has ML fit

$\hat{\pi} = \hat{\alpha} + \hat{\beta}x = .0025 + .0011x$

At $x = 0$, $\hat{\pi} = \hat{\alpha} = .0025$

$\hat{\pi}$ increases by $\hat{\beta} = .0011$ for each 1-unit increase in alcohol consumption.
Note

- ML estimates $\hat{\alpha}$, $\hat{\beta}$ obtained by iterative numerical optimization.

- To test $H_0 : \beta = 0$ (independence), can use

$$z = \frac{\hat{\beta} - 0}{SE(\hat{\beta})}$$

(for large $n$ has approx std. normal dist. under null)

ex. $z = \frac{.0011}{.0007} = 1.50$

For $H_a : \beta \neq 0$, $P$-value = 0.13

Or, $z^2$ approx. $\chi^2_1$ (ex. $z^2 = 2.24$)

- Could use Pearson $X^2$ (or $G^2$) to test indep., but ignores ordering of rows

- Alternative way to apply $X^2$ (or deviance $G^2$) is to test fit of model. (see printout)

(compare counts to values predicted by linear model)
• Same fit if enter 5 binomial “success totals” or the 32,574 individual binary responses of 0 or 1.

• Model \( \pi(x) = \alpha + \beta x \) can give \( \hat{\pi} > 1 \) or \( \hat{\pi} < 0 \)

More realistic models are nonlinear in shape of \( \pi(x) \).
Logistic regression model

\[
\log \left[ \frac{\pi}{1 - \pi} \right] = \alpha + \beta x
\]

is GLM for binomial \( Y \) with logit link

**ex.** \( \logit(\hat{\pi}) = \log \left( \frac{\hat{\pi}}{1 - \hat{\pi}} \right) = -5.96 + .32x \)

\( \hat{\pi} \uparrow \) as \( x \uparrow \), and \( P \)-value = .012 for \( H_o : \beta = 0 \).

(but, \( P = .30 \) if delete “present” obs. in \( \geq 6 \) drinks!!)

**Note**

- Chap. 4 studies this model

- For contingency table, one can test \( H_o : \) model fits, using estimated expected frequencies that satisfy the model, with \( X^2, G^2 \) test stat.’s.

  **ex.** \( X^2 = 2.05, G^2 = 1.95 \) for \( H_o : \) logistic regr. model

  \( df = 3 = 5 \) binom. observ. - 2 parameters (\( P \)-value large, no evidence against \( H_o \))
Both the linear probability model and logistic regression model fit adequately how can this be?

logistic \approx \text{linear when } \hat{\pi} \text{ near 0 or near 1 for all observed } x.
GLMs for count data

When \( Y \) is a count \((0,1,2,3,...)\) traditional to assume Poisson dist.

\[
P(y) = \frac{e^{-\mu} \mu^y}{y!}, \quad y = 0, 1, 2, \ldots
\]

- \( \mu = E(y) \)

\[
\mu = Var(Y), \quad \sigma = \sqrt{\mu}
\]

- In practice often \( \sigma^2 > \mu \), greater variation than Poisson predicts (overdispersion)

- Negative binomial dist. has separate \( \sigma^2 \) parameter and permits overdispersion.
Poisson regression for count data

Suppose we assume $Y$ has Poisson dist., $x$ an explanatory var.

Model $\mu = \alpha + \beta x$ identity link

or $\log(\mu) = \alpha + \beta x$ log link

loglinear model (Ch. 7 for details about this link)

ex. $Y =$ no. defects on silicon wafer

$x =$ treatment $(1 = B, 0 = A)$ dummy (indicator) var.

10 wafers for each

$A : 3, 7, 6, \ldots \quad \bar{y}_A = 5.0$

$B : 6, 9, 8, \ldots \quad \bar{y}_B = 9.0$
For model $\mu = \alpha + \beta x$ (identity link)

$\hat{\mu} = 5.0 + 4.0x$

$x = 0 : \hat{\mu}_A = 5.0 \quad (= \bar{y}_A)$

$x = 1 : \hat{\mu}_B = 9.0 \quad (= \bar{y}_B)$

$\hat{\beta} = 4.0 = \hat{\mu}_B - \hat{\mu}_A$ has $SE = 1.18$

$(\leftarrow \text{test, CI for } \beta)$

For loglinear model $\log(\mu) = \alpha + \beta x$

$log(\hat{\mu}) = 1.609 + .588x$

$x = 0 : \log \hat{\mu}_A = 1.609, \hat{\mu}_A = e^{1.609} = 5.0$

$x = 1 : \log \hat{\mu} = 1.609 + .588 = 2.197, \hat{\mu}_B = e^{2.197} = 9.0$
Inference for GLM parameters

CI: \( \hat{\beta} \pm z_{\alpha/2}(SE) \)

Test: \( H_o : \beta = 0 \)

1. Wald test

\[ z = \frac{\hat{\beta}}{SE} \] has approx. \( N(0,1) \) dist.

For \( H_a : \beta \neq 0 \), can also use Wald stat.

\[ z^2 = \left( \frac{\hat{\beta}}{SE} \right)^2 \] is approx. \( \chi^2_1 \).

CI = set of \( \beta_o \) values for \( H_o : \beta = \beta_o \) such that

\[ |\hat{\beta} - \beta_o|/SE < z_{\alpha/2} \]
2. **Likelihood-ratio test**

\( \ell_0 \) = maximized likelihood when \( \beta = 0 \)

\( \ell_1 \) = maximized likelihood for arbitrary \( \beta \)

Test stat. \( = -2 \log \left( \frac{\ell_0}{\ell_1} \right) \)

\( = -2 \log \ell_0 - (-2 \log \ell_1) \)

\( = -2(L_0 - L_1) \)

Where \( L \) = maximized \( \log \) likelihood
ex. Wafer defects

Loglinear model \( \log(\mu) = \alpha + \beta x \)

\( \beta = \log \mu_B - \log \mu_A \)

\( H_0 : \mu_A = \mu_B \iff \beta = 0 \)

Wald test

\[
z = \frac{\hat{\beta}}{SE} = \frac{0.588}{0.176} = 3.33
\]

\( z^2 = 11.1, \ df = 1, \ P = .0009 \) for \( H_a : \beta \neq 0 \).

Likelihood-ratio test

\( L_1 = 138.2, \ L_0 = 132.4 \)

Test stat. \( -2(L_0 - L_1) = 11.6, \ df = 1 \ P = .0007 \)

PROC GENMOD reports LR test result with ‘type 3’ option
Note

• For very large \( n \), Wald test and likelihood ratio test are approx. equivalent, but for small to moderate \( n \) the LR test is more reliable and powerful.

• LR stat. also equals difference in “deviances,” goodness-of-fit stats.

\[
\text{ex. } 27.86 - 16.27 = 11.59
\]

• LR method also extends to CIs:

\[
100(1 - \alpha)\% \text{ CI} = \text{set of } \beta_o \text{ in } H_0 : \beta = \beta_o \text{ for which } P\text{-value} > \alpha \text{ in LR test.}
\]

(i.e., do not reject \( H_o \) at \( \alpha \)- level)

GENMOD: LRCI option
\[ \beta = \log \mu_B - \log \mu_A = \log \left( \frac{\mu_B}{\mu_A} \right) \]

\[ e^\beta = \frac{\mu_B}{\mu_A} \]

\[ e^{\hat{\beta}} = 1.8 = \frac{\hat{\mu}_B}{\hat{\mu}_A}. \]

95% CI for \( \beta \) is \( .588 \pm 1.96 \times .176 = (.242, .934) \).

95% CI for \( e^\beta = \frac{\mu_B}{\mu_A} \) is

\( (e^{.242}, e^{.934}) = (1.27, 2.54) \).

We’re 95% confident that \( \mu_B \) is between 1.27 and 2.54 times \( \mu_A \).

CI based on likelihood-ratio test is (1.28, 2.56).
Deviance of a GLM

The *saturated model* has a separate parameter for each observation and has the perfect fit $\hat{\mu}_i = y_i$

For a model $M$ with maximized log likelihood $L_M$,

deviance $= -2[L_M - L_S]$, where $S = \text{saturated model}$

$= \text{LR stat. for testing that all parameters not in } M$ equal 0.

i.e., for

$H_o : \text{model holds}$

$H_a : \text{saturated model}$
For Poisson and binomial models for counts,

\[ \text{Deviance} = G^2 = 2 \sum y_i \log \left( \frac{y_i}{\hat{\mu}_i} \right) \leftarrow \text{for } M \]

When \( \hat{\mu}_i \) are large and no. of predictor settings fixed, \( G^2 \) and

\[ X^2 = \sum \frac{(y_i - \hat{\mu}_i)^2}{\hat{\mu}_i} \text{ (Pearson)} \]

are used to test goodness of fit of model (i.e., \( H_0 \): model holds).

They are approx. \( \chi^2 \) with \( df = \text{no. observations} - \text{no. model parameters} \).
ex. Wafer defects

\hat{\mu}_i = 5 \text{ for 10 observ's in Treatment A}

\hat{\mu}_i = 9 \text{ for 10 observ's in Treatment B}

For loglinear model, \( \log \mu = \alpha + \beta x \)

deviance \( G^2 = 16.3 \)

Pearson \( X^2 = 16.0 \)

df = 20 - 2 = 18

These do not contradict \( H_0 : \) model holds,

but their use with chi-square dist. is questionable

• \( \hat{\mu}_i \) not that large

• theory applies for fixed df as \( n \uparrow \) (happens with contingency tables)
Note

• For GLMs one can study lack of fit using residuals (later chapters)

• Count data often show *overdispersion* relative to Poisson GLMs.

  i.e., at fixed \( x \), sample variance > mean, whereas var. = mean in Poisson.

  (often caused by subject *heterogeneity*)

  ex. \( Y \) = no. times attended religious services in past year.

  Suppose \( \mu = 25 \). Is \( \sigma^2 = 25 \) (\( \sigma = 5 \))?
Negative binomial GLM

More flexible model for count that has

\[ E(Y) = \mu, \ Var(Y) = \mu + D\mu^2 \]

where \( D \) called a dispersion para.

As \( D \to 0 \), neg. bin. \to Poisson.

(Can derive as “gamma dist. mixture” of Poissons, where the Poisson mean varies according to a gamma dist.)
ex. GSS data “In past 12 months, how many people have you known personally that were victims of homicide?”

<table>
<thead>

</tbody>
</table>

Model \( \log(\mu) = \alpha + \beta x \)

Black: \( \bar{y} = .52, \ s^2 = 1.15 \)

White: \( \bar{y} = .09, \ s^2 = .16 \)
For Poisson or neg. bin. model,

\[ \log \hat{\mu} = -2.38 + 1.73x \]

\[ e^{1.73} = 5.7 = \frac{.522}{.092} = \frac{\bar{y}_B}{\bar{y}_W} \]

However, SE for \( \hat{\beta} = 1.73 \) is .147 for Poisson, .238 for neg. bin.

Wald 95% CI for \( e^\beta = \mu_B/\mu_W \) is

Poisson: \( e^{1.73\pm1.96(.147)} = (4.2, 7.5) \)

Neg bin: \( e^{1.73\pm1.96(.238)} = (3.5, 9.0) \)

In accounting for overdispersion, neg. bin. model has wider CIs.

LR CIs are \( (e^{1.444}, e^{2.019}) = (4.2, 4.7) \) and \( (3.6, 9.2) \)
For neg. bin. model, estimated dispersion para. $\hat{D} = 4.94$ ($SE = 1.0$)

$$\text{Var}(Y) = \hat{\mu} + \hat{D}\hat{\mu}^2 = \hat{\mu} + 4.94\hat{\mu}^2$$

strong evidence of overdispersion

When $Y$ is a count, safest strategy is to use negative binomial GLM, especially when dispersion para. is significantly $> 0$. 
Models for Rates

When $y_i$ have different bases

(e.g., no. murders for cities with different popul. sizes)

more relevant to model rate at which events occur.

Let $y = \text{count with index } t$

Sample rate $\frac{y}{t}$, $E\left(\frac{Y}{t}\right) = \frac{\mu}{t}$.

Loglinear model $\log \left(\frac{\mu}{t}\right) = \alpha + \beta x$

or $\log(\mu) - \log(t) = \alpha + \beta x$

See text pp. 82-84 for discussion
4. **Logistic Regression**

\[ Y = 0 \text{ or } 1 \]

\[ \pi = P(Y = 1) \]

\[
\log \left[ \frac{\pi(x)}{1 - \pi(x)} \right] = \alpha + \beta x
\]

\[
\text{logit}[\pi(x)] = \log \left[ \frac{\pi(x)}{1 - \pi(x)} \right]
\]

Uses “logit” link for binomial \( Y \). Equivalently,

\[
\pi(x) = \frac{\exp(\alpha + \beta x)}{1 + \exp(\alpha + \beta x)},
\]

where \( \exp(\alpha + \beta x) = e^{\alpha + \beta x} \).

**Properties**

- Sign of \( \beta \) indicates whether \( \pi(x) \) \( \uparrow \) or \( \downarrow \) as \( x \) \( \uparrow \)

- If \( \beta = 0 \), \( \pi(x) = \frac{e^\alpha}{1 + e^\alpha} \) constant as \( x \uparrow \) (\( \pi > \frac{1}{2} \) if \( \alpha > 0 \))

- Curve can be approximated at fixed \( x \) by straight line to describe rate of change.
e.g., at \( x \) with \( \pi(x) = \frac{1}{2} \), slope = \( \beta \left( \frac{1}{2} \right) \left( \frac{1}{2} \right) = \frac{\beta}{4} \).

at \( x \) with \( \pi(x) = 0.1 \) or 0.9, slope = \( \beta (0.1)(0.9) = 0.09\beta \)

Steepest slope where \( \pi(x) = \frac{1}{2} \).

- When \( \pi = \frac{1}{2} \), \( \log \left[ \frac{\pi}{1-\pi} \right] = \log \left[ \frac{0.5}{0.5} \right] = \log(1) = 0 = \alpha + \beta x \longrightarrow x = -\frac{\alpha}{\beta} \) is the \( x \) value where this happens

- \( \frac{1}{\beta} \approx \text{distance between } x \text{ values with } \pi = 0.5 \) and \( \pi = 0.75 \) (or 0.25).

- ML fit obtained with iterative numerical methods.
Ex. Horseshoe crabs

\( Y = 1 \) if female crab has satellites.

\( Y = 0 \) if no satellite.

\( x = \) weight (kg) (\( \bar{x} = 2.44, s = 0.58 \))

\( n = 173 \)

ML fit: logit[\( \hat{\pi}(x) \)] = \(-3.69 + 1.82x\)

or \( \hat{\pi}(x) = \frac{\exp(-3.69+1.82x)}{1+\exp(-3.69+1.82x)} \)

• \( \hat{\beta} > 0 \) so \( \hat{\pi} \uparrow \) as \( x \uparrow \)

• At \( x = \bar{x} = 2.44 \),

\[
\hat{\pi} = \frac{\exp (-3.69 + 1.82(2.44))}{1 + \exp (-3.69 + 1.82(2.44))} = \frac{e^{0.734}}{1 + e^{0.734}} = \frac{2.08}{3.08} = 0.676
\]
• \( \hat{\pi} = \frac{1}{2} \) when \( x = -\frac{\hat{\alpha}}{\hat{\beta}} = \frac{3.69}{1.82} = 2.04 \).

• At \( x = 2.04 \), when \( x \uparrow 1, \hat{\pi} \uparrow \) approx. \( \hat{\beta}\hat{\pi}(1 - \hat{\pi}) = \frac{\hat{\beta}}{4} = 0.45 \).

However, \( s = 0.58 \) for weight, and 1-unit change is too large for this approx. to be good.
(actual \( \hat{\pi} = 0.86 \) at 3.04)

As \( x \uparrow 0.1 \) kg, \( \hat{\pi} \uparrow \) approx \( 0.1\hat{\beta}\hat{\pi}(1 - \hat{\pi}) = 0.045 \)
(actual \( \hat{\pi} = 0.547 \)).

• At \( x = 5.20 \) (max. value), \( \hat{\pi} = 0.997 \). As \( x \uparrow 0.1, \hat{\pi} \uparrow \approx 0.1(1.82)(0.997)(0.003) = 0.0006 \).

Rate of changes varies as \( x \) does.
**Note**

- If we assume $Y \sim \text{Normal}$ and fitted model $\mu = \alpha + \beta x$,

  $$\hat{\mu} = -0.145 + 0.323x$$

  At $x = 5.2$, $\hat{\mu} = 1.53!$ (for estimated prob. of satellite)

- Alternative way to describe effect (not dependent on units) is

  $$\hat{\pi}(x_2) - \hat{\pi}(x_1)$$

  such as $\hat{\pi}(UQ) - \hat{\pi}(LQ)$

**Ex.**

For $x = \text{weight}$, $LQ = 2.00$, $UQ = 2.85$

At $x = 2.00$, $\hat{\pi} = 0.48$; at $x = 2.85$, $\hat{\pi} = 0.81$.

$\hat{\pi}$ increases by 0.33 over middle half of $x$ values.
Odds ratio interpretation

Since \( \log \left( \frac{\pi}{1-\pi} \right) = \alpha + \beta x \), the odds
\[
\frac{\pi}{1-\pi} = e^{\alpha+\beta x}
\]

When \( x \uparrow 1 \), \( \frac{\pi}{1-\pi} = e^{\alpha+\beta(x+1)} = e^\beta e^{\alpha+\beta x} \)

\[ \longrightarrow \text{odds multiply by } e^\beta, \text{ which is } \frac{\text{odds at } x+1}{\text{odds at } x} \]

\[ \beta = 0 \iff e^\beta = 1, \text{ odds stay constant.} \]

Ex. \( \hat{\beta} = 1.82, e^{\hat{\beta}} = 6.1 \)

Estimated odds of satellite multiply by 6.1 for 1 kg increase in weight.

If \( x \uparrow 0.1 \), \( e^{0.1\hat{\beta}} = e^{0.182} = 1.20. \)

Estimated odds increase by 20\%. 
Inference

CI

95% CI for $\beta$ is

$$\hat{\beta} \pm z_{0.025}(SE) \quad \text{(Wald method)}$$

$$1.815 \pm 1.96(0.377), \text{ or } (1.08, 2.55)$$

95% CI for $e^\beta$, multiplicative effect on odds of 1-unit increase in $x$, is

$$(e^{1.08}, e^{2.55}) = (2.9, 12.8).$$

95% CI for $e^{0.1\beta}$ is

$$(e^{0.108}, e^{0.255}) = (1.11, 1.29).$$

(odds increases at least 11%, at most 29%).
Note:

• For small \( n \), safer to use likelihood-ratio CI than Wald CI (can do with LRCI option in SAS GENMOD)

**Ex.** LR CI for \( e^\beta \) is

\[
(e^{1.11}, e^{2.60}) = (3.0, 13.4)
\]

• For binary observation (\( y = 0 \) or \( 1 \)), SAS (PROC GENMOD) can use model statement

\[
\text{model } y = \text{weight/dist = bin} \ldots
\]

but SAS forms logit as \( \log \left[ \frac{P(Y=0)}{P(Y=1)} \right] \) instead of \( \log \left[ \frac{P(Y=1)}{P(Y=0)} \right] \) unless use “descending” option.

e.g., get \( \text{logit}(\hat{\pi}) = 3.69 - 1.82x \) instead of \( \text{logit}(\hat{\pi}) = -3.69 + 1.82x \).

• Software can also construct CI for \( \pi(x) \)

(in SAS, PROC GENMOD or PROC LOGISTIC)

**Ex.** At \( x = 3.05 \) (value for 1st crab), \( \hat{\pi} = 0.863 \). 95% CI for \( \pi \) is

\[
(0.766, 0.924)
\]
Significance Test

\( H_0 : \beta = 0 \) states that \( Y \) indep. of \( X \) (i.e., \( \pi(x) \) constant)

\( H_0 : \beta \neq 0 \)

\[
z = \frac{\hat{\beta}}{SE} = \frac{1.815}{0.377} = 4.8
\]

or Wald stat. \( z^2 = 23.2, df = 1 \) (chi-squared)

P-value < 0.0001

Very strong evidence that weight has positive effect on \( \pi \).

Likelihood-ratio test

When \( \beta = 0 \), \( L_0 = -112.88 \) (log-likelihood under null)

When \( \beta = \hat{\beta} \), \( L_1 = -97.87 \)

Test stat.

\[-2(L_0 - L_1) = 30.0\]

Under \( H_0 \), has approx. \( \chi^2 \) dist. \( df = 1 \) (\( P < 0.0001 \))

(can get using TYPE3 option in GENMOD)
Note: Recall for a model $M$,

$$\text{deviance} = -2(L_M - L_s)$$

$L_s$ means the log-likelihood under saturated (perfect fit) model.

To compare model $M_0$ with a more complex model $M_1$,

$$\text{LR stat.} = -2(L_0 - L_1)$$

$$= -2(L_0 - L_s) - [-2(L_1 - L_s)]$$

$$= \text{diff. of deviances}$$

Ex. $H_0 : \beta = 0$ in logit[$\pi(x)$] = $\alpha + \beta x$ (This is $M_1$).

$M_0 : \text{logit}[$$\pi(x)$$$] = \alpha$

Diff. of deviances = $225.76 - 195.74 = 30.0 = \text{LR statistic}$.
Multiple Logistic Regression

$Y$ binary, $\pi = P(Y = 1)$

$x_1, x_2, \ldots, x_k$ can be quantitative, qualitative (using dummy var’s), or both.

Model form is

$$\text{logit } [P(Y = 1)] = \alpha + \beta_1 x_1 + \beta_2 x_2 \cdots + \beta_k x_k$$

or, equivalently

$$\pi = \frac{e^{\alpha + \beta_1 x_1 + \beta_2 x_2 \cdots + \beta_k x_k}}{1 + e^{\alpha + \beta_1 x_1 + \beta_2 x_2 \cdots + \beta_k x_k}}$$

$\beta_i =$ partial effect of $x_i$, controlling for other var’s in model.

$e^{\beta_i} =$ conditional odds ratio between $Y$ and $x_i$ (1-unit change) keeping other predictors fixed.
**Ex. Horseshoe crab data**

Sampled female has: $Y = 1$, at least 1 “satellite”, $Y = 0$, no satellites.

Let $x =$ weight, $c =$ color (qualitative 4 cat’s).

\[
\begin{align*}
c_1 &= 1 \quad \text{medium light} \\
    c_1 &= 0 \quad \text{otherwise} \\
    c_2 &= 1 \quad \text{medium} \\
    c_2 &= 0 \quad \text{otherwise} \\
    c_3 &= 1 \quad \text{medium dark} \\
    c_3 &= 0 \quad \text{otherwise}
\end{align*}
\]

For dark crabs, $c_1 = c_2 = c_3 = 0$.

**CLASS COLOR** statement in SAS asks SAS to set up dummy variables (indicator) for COLOR (need 3 dummies for 4 categories).
Model:
\[
\text{logit } [P(Y = 1)] = \alpha + \beta_1 c_1 + \beta_2 c_2 + \beta_3 c_3 + \beta_4 x_4
\]
has ML fit
\[
\text{logit } (\hat{\pi}) = -4.53 + 1.27c_1 + 1.41c_2 + 1.08c_3 + 1.69x
\]
e.g., for dark crabs, \( c_1 = c_2 = c_3 = 0 \),
\[
\text{logit } (\hat{\pi}) = -4.53 + 1.69x
\]
At \( x = \bar{x} = 2.44 \),
\[
\hat{\pi} = \frac{\text{e}^{-4.53+1.69(2.44)}}{1 + \text{e}^{-4.53+1.69(2.44)}} = 0.40
\]
For medium light crabs \( (c_1 = 1, c_2 = c_3 = 0) \),
\[
\text{logit } (\hat{\pi}) = -4.53 + 1.27(1) + 1.69x = -3.26 + 1.69x
\]
At \( x = \bar{x} = 2.44 \), \( \hat{\pi} = 0.70 \)
• At each weight, medium-light crabs are more likely than dark crabs to have satellites.

\[
\hat{\beta} = 1.27, \quad e^{1.27} = 3.6
\]

At a given weight, estimated odds a med-light crab has satellite are 3.6 times estimated odds for dark crab.

e.g., at \( x = 2.44 \),

\[
\frac{\text{odds for med-light}}{\text{odds for dark}} = \frac{0.70/0.30}{0.40/0.60} = 3.6
\]

How could you get an estimated odds radio comparing ML to M or MD?

Compare ML \((c_1 = 1)\) to M \((c_2 = 1)\)

\[
1.27 - 1.41 = -0.14, \quad e^{-0.14} = 0.9
\]

At any given weight, estimated odds a ML crab has satellite are 0.9 times estimated odds a M crab has satellite.
Note

• Model assumes lack of interaction between color and weight in effects on $\pi$. This implies coefficient of $x = \text{weight}$ is same for each color ($\hat{\beta}_4 = 1.69$).

i.e., shape of curve for effect of $x$ on $\pi$ is same for each color.

Inference: Do we need color in model?

$H_0 : \beta_1 = \beta_2 = \beta_3 = 0$

Given weight, $Y$ is indep. of color.
Likelihood-ratio test statistic

\[-2(L_0 - L_1) = -2[(-97.9) - (-94.3)] = \text{diff. of deviances} \]
\[= 195.7 - 188.5 = 7.2 \]
\[\text{df} = 171 - 168 = 3, \quad P = 0.07 \]

Some evidence (but not strong) of a color effect, given weight (only 22 “dark” crabs).

Is strong evidence of weight effect (\( \hat{\beta} = 1.69 \) has SE= 0.39).

Given color, estimated odds of satellite at weight \( x + 1 \) equal \( e^{1.69} = 5.4 \) times estimated odds at weight \( x \).
Note Other simple models also adequate.

Ex. for nominal model, color estimates

\( (1.27, 1.41, 1.08, 0) \)
\uparrow \uparrow \uparrow \uparrow
ML \ M \ MD \ D

suggest

\[
\text{logit} \ [P(Y = 1)] = \alpha + \beta_1 x_1 + \beta_2 x_2
\]
where \( x_2 = 0, \) dark , \( x_2 = 1, \) other color.

For it, \( \hat{\beta}_2 = 1.295 \) (SE= 0.522)

Given weight, estimated odds of satellite for nondark crabs = \( e^{1.295} = 3.65 \) times estimated odds for dark crabs.

Does model with 4 separate colors estimates fit better?

\( H_0 : \) simple model (1 dummy)
\( H_a : \) more complex model (3 dummies)

Note; \( H_0 \) is \( \beta_1 = \beta_2 = \beta_3 = 0 \) in more complex model,

\[
\text{logit}[P(Y = 1)] = \alpha + \beta_1 c_1 + \beta_2 c_2 + \beta_3 c_3 + \beta_4 x
\]

LR stat. = diff. in deviance
\[= 189.17 - 188.54 = 0.6 \ (df = 2)\]
Simple model is adequate.

How about model allowing interaction?

\[
\text{logit } [P(Y = 1)] = \alpha + \beta_1 c_1 + \beta_2 c_2 + \beta_3 c_3 + \beta_4 x \\
+ \beta_5 c_1 x + \beta_6 c_2 x + \beta_7 c_3 x
\]

<table>
<thead>
<tr>
<th>Color</th>
<th>Weight effect</th>
<th>(coeff. of ( x ))</th>
</tr>
</thead>
<tbody>
<tr>
<td>dark</td>
<td>( \beta_4 )</td>
<td>((c_1 = c_2 = c_3 = 0))</td>
</tr>
<tr>
<td>med-light</td>
<td>( \beta_4 + \beta_5 )</td>
<td>((c_1 = 1))</td>
</tr>
<tr>
<td>medium</td>
<td>( \beta_4 + \beta_6 )</td>
<td>((c_2 = 1))</td>
</tr>
<tr>
<td>med-dark</td>
<td>( \beta_4 + \beta_7 )</td>
<td>((c_3 = 1))</td>
</tr>
</tbody>
</table>

For \( H_0 \): no interaction \((\beta_5 = \beta_6 = \beta_7 = 0)\)

\[
\text{LR stat.} = -2(L_0 - L_1) = 6.88, \text{ df}=3, \text{ P-value} = 0.08.
\]

Weak evidence of interaction.

For easier interpretation, use simpler model.
**Ordinal factors**

Models with dummy var’s treat color as qualitative (nominal).

To treat as quantitative, assign scores such as (1, 2, 3, 4) and model trend.

\[
\text{logit} = \alpha + \beta_1 x_1 + \beta_2 x_2
\]

\(x_1\) : weight, \(x_2\) : color.

ML fit:

\[
\text{logit} (\hat{\pi}) = -2.03 + 1.65x_1 - 0.51x_2
\]

SE for \(\hat{\beta}_1\) is 0.38, SE for \(\hat{\beta}_2\) is 0.22.

\(\hat{\pi} \downarrow\) as color \(\uparrow\) (more dark), controlling for weight.

\[e^{-0.51} = 0.60\]

which is estimated odds ratio for 1-category increase in darkness.
Does model treating color as nominal fit better?

\[ H_0 : \text{ simpler (ordinal) model holds} \]

\[ H_a : \text{ more complex (nominal) model holds} \]

\[
\text{LR stat.} = -2(L_0 - L_1) \\
= \text{ diff. in deviances} \\
= 190.27 - 188.54 = 1.7, \quad \text{df} = 2
\]

Do not reject \( H_0 \).

Simpler model is adequate.
Qualitative predictors

Ex. FL death penalty revisited

<table>
<thead>
<tr>
<th>Victims’ race</th>
<th>Defendant’s race</th>
<th>Death Penalty</th>
<th></th>
<th></th>
<th>n</th>
</tr>
</thead>
<tbody>
<tr>
<td>B</td>
<td>B</td>
<td>Yes</td>
<td>4</td>
<td>139</td>
<td>143</td>
</tr>
<tr>
<td></td>
<td>W</td>
<td>No</td>
<td>0</td>
<td>16</td>
<td>16</td>
</tr>
<tr>
<td>W</td>
<td>B</td>
<td>Yes</td>
<td>11</td>
<td>37</td>
<td>48</td>
</tr>
<tr>
<td>W</td>
<td>W</td>
<td>No</td>
<td>53</td>
<td>414</td>
<td>467</td>
</tr>
</tbody>
</table>

\[ \pi = P(Y = \text{yes}) \]

\[ v = 1 \quad \text{victims black} \]

\[ d = 0 \quad \text{victims white} \]

\[ d = 1 \quad \text{defendant black} \]

\[ d = 0 \quad \text{defendant white} \]

Model

\[ \logit (\pi) = \alpha + \beta_1 d + \beta_2 v \]

has ML fit

\[ \logit (\hat{\pi}) = -2.06 + 0.87d - 2.40v \]

\[ e^{0.87} = 2.38 \] times

95% CI is:

\[ e^{0.87 \pm 1.96(0.367)} = (1.16, 4.89) \]
Note
• Lack of interaction term means estimated odds ratio between $Y$ and $d$ same at each level of $v$ ($e^{0.87} = 2.38$)

$v$ same at each level of $d$ ($e^{-2.40} = 0.09$)

$(e^{2.40} = \frac{1}{0.09}) = 11.1$

i.e., cont. for $d$, est. odds of death pen. when $v = \text{white}$ were 11.1 times est. odds when $v = \text{black}$.

(homogeneous association) means same odds ratio at each level of other var.

• $H_0 : \beta_1 = 0$ ($Y$ conditional indep. of $d$ given $v$)

$H_a : \beta_1 \neq 0$

$$z = \frac{\hat{\beta}_1}{\text{SE}} = \frac{0.868}{0.367} = 2.36$$

or Wald stat. $z^2 = 5.59$, $df = 1$, $P = 0.018$.

Evidence that death penalty more likely for black def’s, controlling for $v$. 

107
Likelihood-ratio test
Test of $H_0 : \beta_1 = 0$. Compares models

$$H_0 : \logit (\pi) = \alpha + \beta_2 v$$

$$H_a : \logit (\pi) = \alpha + \beta_1 d + \beta_2 v$$

LR stat. $= -2(L_0 - L_1)$
$= 2(211.99 - 209.48) = 5.0$
$= \text{diff. of deviances}$
$= 5.39 - 0.38 = 5.01, \ df = 1 (P = 0.025)$

Exercise

• Conduct Wald, LR, test of $H_0 : \beta_2 = 0$

• Get point and interval estimate of odds ratio for effect of victim’s race, controlling for $d$.

what if $v = 1$ is white, $v = 0$ is black?
Note

- A common application for logistic regression having multiple $2 \times 2$ tables is multi-center clinical trials.

<table>
<thead>
<tr>
<th>Center</th>
<th>Treatment</th>
<th>Response</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>S</td>
<td>F</td>
</tr>
<tr>
<td>1</td>
<td>1</td>

<td>2</td>
<td></td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td></td>
</tr>
<tr>
<td></td>
<td>2</td>
<td></td>
</tr>
<tr>
<td>...</td>
<td>...</td>
<td>...</td>
</tr>
<tr>
<td>K</td>
<td>1</td>
<td></td>
</tr>
<tr>
<td></td>
<td>2</td>
<td></td>
</tr>
</tbody>
</table>

\[
\text{logit} \left[ P(Y = 1) \right] = \alpha + \beta_1 c_1 + \beta_2 c_2 + \cdots + \beta_{K-1} c_{K-1} + \beta x
\]

Assumes odds ratio $= e^{\beta}$ in each table.
A model like this with several dummy var’s for a factor is often expressed as

$$\text{logit } [P(Y = 1)] = \alpha + \beta^c_i + \beta x$$

$\beta^c_i$ is effect for center $i$ (relative to last center).

To test $H_0 : \beta = 0$ about treatment effect for several $2 \times 2$ tables, could use

- likelihood-ratio test
- Wald test
- Cochran-Mantel-Haenszel test (p. 114)
- Small-sample generalization of Fisher’s exact test (pp. 158–159)
Ex. Exercise 4.19

$Y = \text{support current abortion laws}(1 = \text{yes, } 0 = \text{no})$.

\[
\text{logit } [P(Y = 1)] = \alpha + \beta^G_h + \beta^R_i + \beta^P_j + \beta x,
\]

where $\beta^G_h$ is for gender, $\beta^R_i$ is for religion, and $\beta^P_j$ is for party affil.

For religion (Protestant, Catholic, Jewish)

$\hat{\beta}_1^R = -0.57, \hat{\beta}_2^R = -0.66, \hat{\beta}_3^R = 0.0$

$\beta^R_i$ represents terms

$\hat{\beta}_1^R r_1 + \hat{\beta}_2^R r_2 = -0.57r_1 - 0.66r_2$,

where $r_1 = 1$, Prot.; $r_1 = 0$, other, and $r_2 = 1$, Cath.; $r_2 = 0$, other.
Chapter 5: Building Logistic Regression Models

• Model selection

• Model checking

• Be careful with “sparse” categorical data (infinite estimates possible).

Model Selection with Many Predictors

Ex. Horseshoe crab study

\[ Y = \text{whether female crab has satellites} \]
\[ (1 = \text{yes}, 0 = \text{no}). \]

Explanatory variables

• Weight

• Width

• Color(ML, M, MD, D), dummy var’s \( c_1, c_2, c_3 \).

• Spine condition (3 categories), dummy var’s \( s_1, s_2 \).
Consider model for crabs:

\[
\logit[P(Y = 1)] = \alpha + \beta_1 c_1 + \beta_2 c_2 + \beta_3 c_3 \\
+ \beta_4 s_1 + \beta_5 s_2 + \beta_6 (weight) + \beta_7 (width)
\]

LR test of \(H_0: \beta_1 = \beta_2 = \cdots = \beta_7 = 0\) has test stat.

\[-2(L_0 - L_1) = \text{difference of deviances} \]
\[= 225.8 - 185.2 = 40.6 \]
\[\text{df} = 7 \ (P < 0.0001)\]

Strong evidence at least one predictor has an effect.

But, . . . , look at Wald tests of individual effects! (e.g., weight)

\underline{Multicollinearity (strong correlations among predictors)} also plays havoc with GLMs.

\text{e.g. } \text{corr}(weight, width) = 0.89

Partial effect of either relevant? Sufficient to pick one of these for a model.
Ex. Using backward elimination

- Use $W = \text{width}$, $C = \text{color}$, $S = \text{spline}$ as predictors.
- Start with complex model, including all interactions.
- Drop “least significant” (e.g., largest P-value) variable among highest-order terms.
- Refit model
- Continue until all variables left are significant.

**Note:** If testing many interactions, simpler and perhaps better to test at one time as a group of terms.
Ex. $H_0$ : Model $C + S + W$ has 3 parameters for $C$, 2 parameters for $S$, 1 parameter for $W$.

$H_a$ : Model

\[
C \ast S \ast W = C + S + W + C \times S \\
+ C \times W + S \times W + C \times S \times W
\]

LR stat. = diff. in deviances

\[
= 186.6 - 170.4 = 16.2
\]

df = 166 - 152 = 14 ($P = 0.30$)

Simpler model $C + S + W$ is adequate.

At next stage, $S$ can be dropped from model $C + S + W$.

\[
\text{diff. in deviances} = 187.5 - 186.6 = 0.9, \text{ df } = 2.
\]
Results in model fit (see text for details)

\[
\logit(\hat{\pi}) = -12.7 + 1.3c_1 + 1.4c_2 + 1.1c_3 + 0.47(\text{width})
\]

Setting \(\beta_1 = \beta_2 = \beta_3\) gives

\[
\logit(\hat{\pi}) = -13.0 + 1.3c + 0.48(\text{width})
\]

where \(c = 1, \text{ML, M, MD};\ c = 0, \text{D.}\)

Conclude

- Given width, estimated odds of satellite for nondark crabs equal \(e^{1.3} = 3.7\) times est. odds for dark crabs.

\[95\% \text{ CI: } e^{1.3\pm 1.96(0.525)} = (1.3, 10.3)\]

(wide CI reflects small number of dark crabs in sample)

- Given color, estimated odds of satellite multiplied by \(e^{0.48\pm 1.96(0.104)} = (1.3, 2.0)\) for each 1 cm increase in width.
Criteria for selecting a model

- Use theory, other research as guide.

- Parsimony (simplicity) is good.

- Can use some criterion to choose among set of models. Most popular criterion is Akaike information criterion (AIC): Chooses model with minimum

\[
AIC = -2(L - \text{no. model parameters})
\]

where \( L = \log \text{likelihood} \).

- For exploratory purpose, can use automated procedure such as backward elimination.

- Ideally should have \( \geq 10 \) outcomes of each type per predictor.

Ex. \( n = 1000, (Y = 1) 30 \) times, \( (Y = 0) 970 \) times. Model should contain \( \leq 3 \) predictors.

Ex. \( n = 173 \) horseshoe crabs. \( (Y = 1): 111 \) crabs; \( (Y = 0): 62 \) crabs. Use \( \leq 6 \) predictors.
Note

- Some software (e.g. PROC LOGISTIC in SAS) has options for stepwise selection procedures.

- Can further check fit with residuals for grouped data, influence measures, cross validation.

- To summarize predictive power, can use correlation($Y, \hat{\pi}$).

<table>
<thead>
<tr>
<th>Predictors</th>
<th>Correlation</th>
</tr>
</thead>
<tbody>
<tr>
<td>color</td>
<td>0.28</td>
</tr>
<tr>
<td>width</td>
<td>0.40</td>
</tr>
<tr>
<td>color+width</td>
<td>0.452</td>
</tr>
<tr>
<td>color=dark+width</td>
<td>0.447</td>
</tr>
</tbody>
</table>

Another summary: Classification table

Predict $\hat{Y} = 1$ if $\hat{\pi} > 0.50$ and $\hat{Y} = 0$ if $\hat{\pi} < 0.50$

<table>
<thead>
<tr>
<th>Actual</th>
<th>$\hat{Y} = 1$</th>
<th>$\hat{Y} = 0$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$Y = 1$</td>
<td>94</td>
<td>17</td>
</tr>
<tr>
<td>$Y = 0$</td>
<td>34</td>
<td>28</td>
</tr>
</tbody>
</table>

Sensitivity=$P(\hat{Y} = 1|Y = 1) = \frac{94}{94+17} = 0.85$

Specificity=$P(\hat{Y} = 0|Y = 0) = \frac{28}{28+34} = 0.45$
SAS: Get with CTABLE option in PROC LOGISTIC, for various “cutpoints”.

SPSS: Get with BINARY LOGISTIC choice on REGRESSION menu.

Model checking

Is the chosen model adequate?

- Goodness of fit test
  But, tests using deviance $G^2$, $X^2$ limited to “nonsparse” contingency tables.

- Check whether fit improves by adding other predictors, interactions between predictors.

  LR stat. = change in deviance is useful for comparing models even when $G^2$ not valid as overall test of fit.
EX. Florida death penalty data

<table>
<thead>
<tr>
<th>Victim Race</th>
<th>Defendant Race</th>
<th>Death penalty (Y)</th>
<th>n</th>
</tr>
</thead>
<tbody>
<tr>
<td>B</td>
<td>B</td>
<td>Yes: 4</td>
<td>139</td>
</tr>
<tr>
<td>W</td>
<td>0</td>
<td>Yes: 16</td>
<td>16</td>
</tr>
<tr>
<td>W</td>
<td>B</td>
<td>Yes: 11</td>
<td>37</td>
</tr>
<tr>
<td>W</td>
<td>53</td>
<td>Yes: 414</td>
<td>467</td>
</tr>
</tbody>
</table>

\[ \pi = P(Y = \text{yes}) \]

**Goodness of fit**

For model fit with \( d = 1 \) (black def.) or \( d = 1 \) (white def.) and \( v = 1 \) (black vic.) and \( v = 0 \) (white vic.),

\[
\text{logit } (\hat{\pi}) = -2.06 + 0.87d - 2.40v,
\]

\[
\hat{\pi} = \frac{e^{-2.06+0.87d-2.40v}}{1 + e^{-2.06+0.87d-2.40v}}
\]

e.g., for 467 cases with white def., victim, \( d = v = 0 \),

\[ \hat{\pi} = \frac{e^{-2.06}}{1 + e^{-2.06}} = 0.113. \]

Fitted count “Yes” = 467(0.113) = 52.8
Fitted count “No” = 467(0.887) = 414.2
Observed counts = 53 and 414

Summarizing fit over 8 cells,

\[ X^2 = \sum \frac{(\text{obs} - \text{fit})^2}{\text{fit}} = 0.20 \]

\[ G^2 = 2 \sum \text{obs} \log \frac{\text{obs}}{\text{fit}} = 0.38 \]

= deviance for model

\[ \text{df} = 4 - 3 = 1 \]

4 = no. binomial observ’s, 3 = no. model parameters.

For \( G^2 = 0.38 \), \( P = 0.54 \) for \( H_0 \) : model holds
(no evidence of lack of fit).

**Note**

- Model assumes lack of interaction between \( d \) and \( v \) in effects on \( Y \), so goodness of fit test in this example is a test of \( H_0 \): no interaction.

- For continuous predictors or many predictors with small \( \mu_i \), \( X^2 \) and \( G^2 \) are not approx. \( \chi^2 \). For better approx., can group data before applying \( X^2, G^2 \).

Hosmer-Lemeshow test groups using ranges of \( \hat{\pi} \) values
(available in PROC LOGISTIC).

Or, can try to group predictor values (if only 1 or 2 predictors).

Residuals for Logistic Regression

At setting $i$ of explanatory var’s, let

$y_i = \text{no. successes}$

$n_i = \text{no. trials (preferably “large”)}$  

$\hat{\pi} = \text{estimated prob. of success,}$

based on ML model fit

For a binomial GLM, Pearson residuals are

$e_i = \frac{y_i - n_i \hat{\pi}_i}{\sqrt{n_i \hat{\pi}_i (1 - \hat{\pi}_i)}}$

$(X^2 = \sum_i e_i^2)$

$e_i$ (called Reschi in SAS GENMOD) is approx. $N(0, v)$, when model holds, but $v < 1.$

Standardized Pearson residual (adjusted residual in some books, SPSS)

$r_i = \frac{y_i - n_i \hat{\pi}_i}{\text{SE}} = \frac{e_i}{\sqrt{1 - h_i}}$
where $h_i$ is called “leverage” ($r_i$ labelled StReschi in SAS).

$r_i$ is approx. $N(0, 1)$ when model holds.

$|r_i| > 2$ or 3 (approx.) suggests lack of fit.

EX. $Y =$ admitted into graduate school at Berkeley (1=yes, 0=no). Data on p. 237 of text.

$G =$gender ($g = 0$ female, $g = 1$ male).

$D =$ department (A, B, C, D, E, F).

$d_1 = 1$, dept. A; $d_1 = 0$, otherwise

\cdots

$d_5 = 1$, dept. E; $d_5 = 0$, otherwise

For department F, $d_1 = d_2 = \cdots = d_5 = 0$. 
• Model

\[ \text{logit } [P(Y = 1)] = \alpha + \beta_1 d_1 + \cdots + \beta_5 d_5 + \beta_6 g \]

seems to fit poorly (deviance \( G^2 = 20.2, \text{df}=5, P=0.01 \))

• Simpler models fit poorly. e.g., model with \( \beta_6 = 0 \) assumes \( Y \) indep. of \( G \), controlling for \( D \), has

\[ G^2 = 21.7, \text{df} = 6, P = 0.001 \]

Apparently, there is a gender \( \times \) dept. interaction.

Residual analysis indicates lack of fit only for dept. A (Standardized Pearson residual= \( \pm4.15 \) in model 2).

In other depts., model with no gender effect is adequate.

Note • In dept. A, \( \hat{\theta} = 0.35 \) (odds of admission lower for males)

• Alternative way to express model with qualitative factor is

\[ \text{logit } = [P(Y = 1)] = \alpha + \beta_i^X + \beta_k^Z, \]

where \( \beta_i^X \) is effect of classification in category \( i \) of \( X \).

Sparse data

**Caution**: Parameter estimates in logistic regression can be infinite.

**Ex.**

<table>
<thead>
<tr>
<th></th>
<th>S</th>
<th>F</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>8</td>
<td>2</td>
</tr>
<tr>
<td>0</td>
<td>10</td>
<td>0</td>
</tr>
</tbody>
</table>

Model

\[
\log \left[ \frac{P(S)}{P(F)} \right] = \alpha + \beta x
\]

\[e^{\hat{\beta}} = \text{odds ratio} = \frac{8 \times 0}{2 \times 10} = 0\]

\[\hat{\beta} = \log \text{odds ratio} = -\infty.\]

**Ex.** Text p.155 for multi-center clinical trial (5 centers, each with 2 × 2 table)
Ex. $y = 0$ for $x < 50$ and $y = 1$ for $x > 50$.

$$\text{logit}[P(Y = 1)] = \alpha + \beta x$$

has $\hat{\beta} = \infty$. Software may not realize this!

**PROC GENMOD**

$\hat{\beta} = 3.84$, \(SE= 15601054\).

**PROC LOGISTIC** gives warning

**SPSS**

$\hat{\beta} = 1.83$, \(SE= 674.8\).

Infinite estimates exists when can separate $x$-values where $y = 1$ from $x$-values where $y = 0$ (perfect discrimination).
Ch 6: Multicategory Logit Models

$Y$ has $J$ categories, $J > 2$.

Extensions of logistic regression for nominal and ordinal $Y$ assume a multinomial distribution for $Y$.

Model for Nominal Responses

Let $\pi_j = P(Y = j)$, $j = 1, 2, \ldots, J$

Baseline-category logits are

$$\log \left( \frac{\pi_j}{\pi_J} \right), \ j = 1, 2, \ldots, J - 1.$$ 

Baseline-category logit model has form

$$\log \left( \frac{\pi_j}{\pi_J} \right) = \alpha_j + \beta_j x, \ j = 1, 2, \ldots, J - 1.$$ 

i.e., separate set of parameters $(\alpha_j, \beta_j)$ occurs for each logit (for each predictor).
Note:

- Which category we use as the baseline category (i.e., cat. J) is arbitrary (For nominal variables, the order of the categories is arbitrary).

- $\exp(\hat{\beta}_j)$ is the multiplicative impact of a 1-unit increase in $x$ on the odds of making response $j$ instead of response $J$.

- Can use model with ordinal response variables also, but then you ignore information about ordering.
Ex. Income and job satisfaction (1991 GSS data)

<table>
<thead>
<tr>
<th>INCOME ($ 1000)</th>
<th>JOB SATISFACTION</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Very dissatisfied</td>
</tr>
<tr>
<td>&lt; 5</td>
<td>2</td>
</tr>
<tr>
<td>5-15</td>
<td>2</td>
</tr>
<tr>
<td>15-25</td>
<td>0</td>
</tr>
<tr>
<td>&gt; 25</td>
<td>0</td>
</tr>
</tbody>
</table>

Using $x =$income scores (3, 10, 20, 30), we use SAS (PROC LOGISTIC) to fit model

$$\log \left( \frac{\hat{\pi}_j}{\hat{\pi}_4} \right) = \alpha_j + \beta_j x, \quad j = 1, 2, 3,$$

for $J = 4$ job satisfaction categories

SPSS: fit using MULTINOMIAL LOGISTIC suboption under REGRESSION option in ANALYZE menu

Prediction equations

$$\log \left( \frac{\hat{\pi}_1}{\hat{\pi}_4} \right) = 0.56 - 0.20x$$

$$\log \left( \frac{\hat{\pi}_2}{\hat{\pi}_4} \right) = 0.65 - 0.07x$$

$$\log \left( \frac{\hat{\pi}_3}{\hat{\pi}_4} \right) = 1.82 - 0.05x$$
Note

- For each logit, odds of being in less satisfied category (instead of very satisfied) decrease as $x = \text{income} \uparrow$.

- The estimated odds of being “very dissatisfied” instead of “very satisfied” multiplies by $e^{-0.20} = 0.82$ for each 1 thousand dollar increase in income.

For a 10 thousand dollar increase in income, (e.g., from row 2 to row 3 or from row 3 to row 4 of table), the estimated odds multiply by

$$e^{10(-0.20)} = e^{-2.0} = 0.14.$$  

E.g, at $x = 30$, the estimated odds of being “very dissatisfied” instead of “very satisfied” are just 0.14 times the corresponding odds at $x = 20$.

- Model treats income as quantitative, $Y = \text{job satisfaction}$ as qualitative (nominal), but $Y$ is ordinal. (We later consider a model that treats job satisfaction as ordinal.)
Estimating response probabilities

Equivalent form of model is

\[ \pi_j = \frac{e^{\alpha_j + \beta_j x}}{1 + e^{\alpha_1 + \beta_1 x} + \cdots + e^{\alpha_{J-1} + \beta_{J-1} x}}, \quad j = 1, 2, \ldots, J-1 \]

\[ \pi_J = \frac{1}{1 + e^{\alpha_1 + \beta_1 x} + \cdots + e^{\alpha_{J-1} + \beta_{J-1} x}} \]

Then,

\[ \frac{\pi_j}{\pi_J} = e^{\alpha_j + \beta_j x} \]

\[ \log \left( \frac{\pi_j}{\pi_J} \right) = \alpha_j + \beta_j x \]

Note \( \sum \pi_j = 1 \).
**Ex. Job satisfaction data**

\[ \hat{\pi}_1 = \frac{e^{0.56-0.20x}}{1 + e^{0.56-0.20x} + e^{0.65-0.07x} + e^{1.82-0.05x}} \]

\[ \hat{\pi}_2 = \frac{e^{0.65-0.07x}}{1 + e^{0.56-0.20x} + e^{0.65-0.07x} + e^{1.82-0.05x}} \]

\[ \hat{\pi}_3 = \frac{e^{1.82-0.05x}}{1 + e^{0.56-0.20x} + e^{0.65-0.07x} + e^{1.82-0.05x}} \]

\[ \hat{\pi}_4 = \frac{1}{1 + e^{0.56-0.20x} + e^{0.65-0.07x} + e^{1.82-0.05x}} \]

e.g. at \( x = 30 \), estimated prob. of “very satisfied” is

\[ \hat{\pi}_4 = \frac{1}{1 + e^{0.56-0.20x} + e^{0.65-0.07x} + e^{1.82-0.05x}} = 0.365. \]

Likewise, \( \hat{\pi}_1 = 0.002 \), \( \hat{\pi}_2 = 0.084 \), \( \hat{\pi}_3 = 0.550 \)

\[ \hat{\pi}_1 + \hat{\pi}_2 + \hat{\pi}_3 + \hat{\pi}_4 = 1.0 \]
• ML estimates determine effects for all pairs of categories, e.g.

\[
\log \left( \frac{\hat{\pi}_1}{\hat{\pi}_2} \right) = \log \left( \frac{\hat{\pi}_1}{\hat{\pi}_4} \right) - \log \left( \frac{\hat{\pi}_2}{\hat{\pi}_4} \right) \\
= (0.564 - 0.199x) - (0.645 - 0.070x) \\
= -0.081 - 0.129x
\]

• Contingency table data, so can test goodness of fit

The deviance is the LR test statistic for testing that all parameters not in model = 0.

Deviance = \( G^2 = 4.18 \), \( df = 6 \), \( P\)-value = 0.65 for \( H_0 \) : Model holds with linear trends for income

(Also, Pearson \( X^2 = 3.6 \), \( df = 6 \), \( P = 0.73 \) for same hypothesis)

Model has 12 logits (3 at each of 4 income levels), 6 parameters, so \( df = 12 - 6 = 6 \) for testing fit.
Note: Inference uses usual methods

- Wald CI for $\beta_j$ is $\hat{\beta}_j \pm z(SE)$

- Wald test of $H_0: \beta_j = 0$ uses $z = (\hat{\beta}_j/SE)$ or $z^2 \sim \chi^2_1$

- For small $n$, better to use LR test, LR CI

Ex. Overall “global” test of income effect

$H_0: \beta_1 = \beta_2 = \beta_3 = 0$

SAS reports Wald statistic = 7.03, $df = 3$, $P = 0.07$

Weak evidence, but ignores ordering of satisfaction categories.

(With many parameters, Wald stat. = quadratic form $\hat{\beta}'[Cov(\hat{\beta})]^{-1}\hat{\beta}$)

Can get LR statistic by comparing deviance with simpler “independence model”

LR stat. = 9.29, $df = 3$, $P = 0.03.$
Model for Ordinal Responses

The cumulative probabilities are

\[ P(Y \leq j) = \pi_1 + \ldots + \pi_j, \quad j = 1, 2, \ldots, J. \]

Cumulative logits are

\[
\text{logit} [P(Y \leq j)] = \log \left[ \frac{P(Y \leq j)}{1 - P(Y \leq j)} \right] \\
= \log \left[ \frac{P(Y \leq j)}{P(Y > j)} \right] = \log \left[ \frac{\pi_1 + \ldots + \pi_j}{\pi_{j+1} + \ldots + \pi_J} \right]
\]

for

\[ j = 1, 2, \ldots, J - 1 \]

Cumulative logit model has form

\[ \text{logit} [P(Y \leq j)] = \alpha_j + \beta x \]

- separate intercept \( \alpha_j \) for each cumulative logit
- same slope \( \beta \) for each cumulative logit
Note

- \( e^\beta \) = multiplicative effect of 1-unit change in \( x \) on odds that \((Y \leq j)\) (instead of \((Y > j)\))

- \[
\frac{\text{odds of } (Y \leq j) \text{ at } x_2}{\text{odds of } (Y \leq j) \text{ at } x_1} = e^{\beta(x_2-x_1)}
\]

\[
= e^{\beta} \quad \text{when } x_2 = x_1 + 1
\]

Also called proportional odds model.

Software notes

- SAS: ML fit with PROC LOGISTIC, PROC GENMOD (dist=mult, link=clogit)

PROC LOGISTIC default for dummy variable is 1 in category, -1 if in last category, 0 otherwise.

To use usual form of 1 in category, 0 otherwise, use param = ref option, e.g.,

CLASS race gender / param = ref ;
SPSS:

ANALYZE $\rightarrow$ REGRESSION $\rightarrow$ ORDINAL to get cumulative logit model but estimates $\hat{\beta}$ have opposite sign as in SAS (as in modeling log[$P(Y > j)/P(Y \leq j)$])

**Ex.** Job satisfaction and income

$$\text{logit } [\hat{P}(Y \leq j)] = \hat{\alpha}_j + \hat{\beta}x = \hat{\alpha}_j - 0.056x, \quad j = 1, 2, 3$$

Odds of response at low end of job satisfaction scale ↓ as $x = \text{income}$ ↑

$$e^{\hat{\beta}} = e^{-0.056} = 0.95$$

Estimated odds of satisfaction below any given level (instead of above it) multiplies by 0.95 for 1-unit increase in $x$ (but, $x = 3, 10, 20, 30$)

For $10,000$ increase in income, estimated odds multiply by

$$e^{10\hat{\beta}} = e^{10(-0.056)} = 0.57$$

e.g., estimated odds of satisfaction being below (instead of above) some level at $30,000$ income equal 0.57 times the odds at $20,000$. 

138
Note

- If reverse order, $\hat{\beta}$ changes sign but has same SE.

Ex. Category 1 = Very satisfied, 2 = Moderately satisfied, 3 = little dissatisfied, 4 = Very dissatisfied

$\hat{\beta} = 0.056, e^{\hat{\beta}} = 1.06 = 1/0.95$

(Response more likely at “very satisfied” end of scale as $x \uparrow$)

- $H_0 : \beta = 0$ (job satisfaction indep. of income) has

  \[
  \text{Wald stat.} = \left( \frac{\hat{\beta} - 0}{SE} \right)^2 = \left( \frac{-0.056}{0.021} \right)^2 = 7.17
  \]

  ($df = 1, P = 0.007$)

LR statistic = 7.51 ($df = 1, P = 0.006$)
These tests give stronger evidence of association than if treat:

- **Y** as nominal (BCL model),

\[
\log \left( \frac{\pi_j}{\pi_4} \right) = \alpha_j + \beta_j x
\]

(Recall \( P = 0.07 \) for Wald test of \( H_0 : \beta_1 = \beta_2 = \beta_3 = 0 \))

- **X, Y** as nominal

Pearson test of indep. has \( X^2 = 11.5, \ df = 9, P = 0.24 \)

(analogous to testing all \( \beta_j = 0 \) in BCL model with dummy predictors).

With BCL or cumulative logit models, can have quantitative and qualitative predictors, interaction terms, etc.
Ex. $Y =$ political ideology (GSS data)  
(1 = very liberal, ..., 5 = very conservative)

$x_1 =$ gender (1 = F, 0 = M)

$x_2 =$ political party (1 = Democrat, 0 = Republican)

ML fit

$$\text{logit } [\hat{P}(Y \leq j)] = \hat{\alpha}_j + 0.117x_1 + 0.964x_2$$

For $\hat{\beta}_1 = 0.117$, $SE = 0.127$
For $\hat{\beta}_2 = 0.964$, $SE = 0.130$

For each gender, estimated odds a Democrat’s response is in liberal rather than conservative direction (i.e., $Y \leq j$ rather than $Y > j$) are $e^{0.964} = 2.62$ times estimated odds for Republican’s response.

- 95% CI for true odds ratio is

$$e^{0.964 \pm 1.96(0.130)} = (2.0, 3.4)$$

- LR test of $H_0 : \beta_2 = 0$ (no party effect, given gender) has test stat. $= 56.8$, $df = 1$ ($P < 0.0001$)

Very strong evidence that Democrats tend to be more liberal than Republicans (for each gender)
Not much evidence of gender effect (for each party)

But, is there interaction?

ML fit of model permitting interaction is

$$\logit [\hat{P}(Y \leq j)] = \hat{\alpha}_j + 0.366x_1 + 1.265x_2 - 0.509x_1x_2$$

For $H_0: \beta_3 = 0$, LR stat. = 3.99, $df = 1$ ($P = 0.046$)

Estimated odds ratio for party effect ($x_2$) is

$$e^{1.265} = 3.5 \text{ when } x_1 = 0 \text{ (M)}$$
$$e^{1.265-0.509} = 2.2 \text{ when } x_1 = 1 \text{ (F)}$$

Estimated odds ratio for gender effect ($x_1$) is

$$e^{0.366} = 1.4 \text{ when } x_2 = 0 \text{ (Republican)}$$
$$e^{0.366-0.509} = 0.9 \text{ when } x_2 = 1 \text{ (Democrat)}$$

i.e., for Republicans, females ($x_1 = 1$) tend to be more liberal that males.
Find $\hat{P}(Y = 1)$ (very liberal) for male Republicans, female Republicans.

$$\hat{P}(Y \leq j) = \frac{e^{\hat{\alpha}_j + 0.366x_1 + 1.265x_2 - 0.509x_1x_2}}{1 + e^{\hat{\alpha}_j + 0.366x_1 + 1.265x_2 - 0.509x_1x_2}}$$

For $j = 1$, $\hat{\alpha}_1 = -2.674$

Male Republicans ($x_1 = 0, x_2 = 0$)

$$\hat{P}(Y = 1) = \frac{e^{-2.674}}{1 + e^{-2.674}} = 0.064$$

Female Republicans ($x_1 = 1, x_2 = 0$)

$$\hat{P}(Y = 1) = \frac{e^{-2.674 + 0.366}}{1 + e^{-2.674 + 0.366}} = 0.090$$

(weak gender effect for Republicans, likewise for Democrats but in opposite direction)

Similarly, $\hat{P}(Y = 2) = \hat{P}(Y \leq 2) - \hat{P}(Y \leq 1)$, etc.

Note $P(Y = 5) = P(Y \leq 5) - P(Y \leq 4) = 1 - P(Y \leq 4)$ (use $\hat{\alpha}_4 = 0.879$)
Note

- If reverse order of response categories

(very lib., slight lib., moderate, slight cons., very cons.) $\rightarrow$

(very cons., slight cons., moderate, slight lib., very liberal)

estimates change sign, odds ratio $\rightarrow 1/(\text{odds ratio})$

- For ordinal response, other orders not sensible.

Ex. categories (liberal, moderate, conservative)

Enter into SAS as 1, 2, 3

or PROC GENMOD ORDER=DATA;

or else SAS will alphabetize as

(conservative, liberal, moderate)

and treat that as ordering for the cumulative logits
Ch 8: Models for Matched Pairs

Ex. Crossover study to compare drug with placebo.

86 subjects randomly assigned to receive drug then placebo or else placebo then drug.
Binary response (S, F) for each

<table>
<thead>
<tr>
<th>Treatment</th>
<th>S</th>
<th>F</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Drug</td>
<td>61</td>
<td>25</td>
<td>86</td>
</tr>
<tr>
<td>Placebo</td>
<td>22</td>
<td>64</td>
<td>86</td>
</tr>
</tbody>
</table>

Methods so far (e.g., $X^2$, $G^2$ test of indep., CI for $\theta$, logistic regression) assume independent samples, they are inappropriate for dependent samples (e.g., same subjects in each sample, which yield matched pairs).

To reflect dependence, display data as 86 observations rather than $2 \times 86$ observations.

<table>
<thead>
<tr>
<th></th>
<th>S</th>
<th>F</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Placebo</td>
<td></td>
<td></td>
<td></td>
</tr>

<td>$\pi_{21}$</td>
<td>$\pi_{22}$</td>
</tr>
<tr>
<td>$\pi_{+1}$</td>
<td>$\pi_{+2}$</td>
<td>1.0</td>
</tr>
</tbody>
</table>

Compare dependent samples by making inference about $\pi_{1+} - \pi_{+1}$.

There is *marginal homogeneity* if $\pi_{1+} = \pi_{+1}$.

**Note:**

$$\pi_{1+} - \pi_{+1} = (\pi_{11} + \pi_{12}) - (\pi_{11} - \pi_{21})$$

$$= \pi_{12} - \pi_{21}$$

So, $\pi_{1+} = \pi_{+1} \iff \pi_{12} = \pi_{21}$ (*symmetry*)

Under $H_0$ : marginal homogeneity,

$$\frac{\pi_{12}}{\pi_{12} + \pi_{21}} = \frac{1}{2}$$

Each of $n^* = n_{12} + n_{21}$ observations has probability $\frac{1}{2}$ of contributing to $n_{12}$, $\frac{1}{2}$ of contributing to $n_{21}$.

$$n_{12} \sim bin(n^*, \frac{1}{2})$$, mean $= \frac{n^*}{2}$, std. dev. $= \sqrt{n^*(\frac{1}{2})(\frac{1}{2})}$. 
By normal approximation to binomial, for large $n^*$

$$z = \frac{n_{12} - n^*/2}{\sqrt{n^*\left(\frac{1}{2}\right)\left(\frac{1}{2}\right)}} \sim N(0, 1)$$

$$= \frac{n_{12} - n_{21}}{\sqrt{n_{12} + n_{21}}}$$

Or,

$$z^2 = \frac{(n_{12} - n_{21})^2}{n_{12} + n_{21}} \sim \chi^2_1$$

called McNemar’s test

**Ex.**

<table>
<thead>
<tr>
<th></th>
<th>Placebo</th>
<th></th>
<th></th>
</tr>

<td>F</td>
<td>10</td>
<td>15</td>
</tr>
<tr>
<td></td>
<td></td>
<td>22</td>
<td>86</td>
</tr>
</tbody>
</table>

$$z = \frac{n_{12} - n_{21}}{\sqrt{n_{12} + n_{21}}} = \frac{49 - 10}{\sqrt{49 + 10}} = 5.1$$

$P < 0.0001$ for $H_0 : \pi_{1+} = \pi_{+1}$ vs $H_a : \pi_{1+} \neq \pi_{+1}$

Extremely strong evidence that probability of success is higher for drug than placebo.
CI for $\pi_{1+} - \pi_{+1}$

Estimate $\pi_{1+} - \pi_{+1}$ by $p_{1+} - p_{+1}$, difference of sample proportions.

$$Var(p_{1+} - p_{+1}) = Var(p_{1+}) + Var(p_{+1}) - 2Cov(p_{1+}, p_{+1})$$

$$SE = \sqrt{\hat{Var}(p_{1+} - p_{+1})}$$

<p>| | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>$n_{11}$</td>
<td>$n_{12}$</td>
<td></td>
</tr>
<tr>
<td>$n_{21}$</td>
<td>$n_{22}$</td>
<td></td>
</tr>
<tr>
<td>$n$</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

12 49
10 15
86

$$p_{1+} - p_{+1} = \frac{n_{11} + n_{12}}{n} - \frac{n_{11} + n_{21}}{n} = \frac{n_{12} - n_{21}}{n} = \frac{49 - 10}{86} = 0.453$$
The standard error of $p_{1+} - p_{+1}$ is

$$\frac{1}{n} \sqrt{(n_{12} + n_{21}) - \frac{(n_{12} - n_{21})^2}{n}}$$

For the example, this is

$$\frac{1}{86} \sqrt{(49 + 10) - \frac{(49 - 10)^2}{86}} = 0.075$$

95% CI is $0.453 \pm 1.96(0.075) = (0.31, 0.60)$.

Conclude we’re 95% confident that probability of success is between 0.31 and 0.60 higher for drug than for placebo.
Measuring agreement (Section 8.5.5)

Ex. Movie reviews by Siskel and Ebert

<table>
<thead>
<tr>
<th></th>
<th>Con</th>
<th>Mixed</th>
<th>Pro</th>
</tr>
</thead>
<tbody>
<tr>
<td>Con</td>
<td>24</td>
<td>8</td>
<td>13</td>
</tr>
<tr>
<td>Siskel</td>
<td>8</td>
<td>13</td>
<td>11</td>
</tr>
<tr>
<td>Pro</td>
<td>10</td>
<td>9</td>
<td>64</td>
</tr>
<tr>
<td></td>
<td>42</td>
<td>30</td>
<td>88</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>160</td>
</tr>
</tbody>
</table>

How strong is their agreement?

Let $\pi_{ij} = P(S = i, E = j)$

$$P(\text{agreement}) = \pi_{11} + \pi_{22} + \pi_{33} = \sum \pi_{ii} = 1 \text{ if perfect agreement}$$

If ratings are independent, $\pi_{ii} = \pi_{i+\pi+i}$

$$P(\text{agreement}) = \sum \pi_{ii} = \sum \pi_{i+\pi+i}$$

Kappa

$$\kappa = \frac{\sum \pi_{ii} - \sum \pi_{i+\pi+i}}{1 - \sum \pi_{i+\pi+i}}$$

$$= \frac{P(\text{agree}) - P(\text{agree|independent})}{1 - P(\text{agree|independent})}$$
Note

• $\kappa = 0$ if agreement only equals that expected under independence.

• $\kappa = 1$ if perfect agreement.

• Denominator = maximum difference for numerator, if perfect agreement.

Ex.

\[
\sum \hat{\pi}_{ii} = \frac{24 + 13 + 64}{160} = 0.63
\]

\[
\sum \hat{\pi}_{i+} \hat{\pi}_{+i} = \left( \frac{45}{160} \right) \left( \frac{42}{160} \right) + \cdots + \left( \frac{83}{160} \right) \left( \frac{88}{160} \right) = 0.40
\]

\[
\hat{\kappa} = \frac{0.63 - 0.40}{1 - 0.40} = 0.389
\]

The strength of agreement is only moderate.
• 95% CI for $\kappa$: $0.389 \pm 1.96(0.06) = (0.27, 0.51)$.

• For $H_0 : \kappa = 0$,

$$z = \frac{\hat{\kappa}}{SE} = \frac{0.389}{0.06} = 6.5$$

There is extremely strong evidence that agreement is better than “chance”.

• In SPSS,

Analyze $\rightarrow$ Descriptive statistics $\rightarrow$ Crosstabs

Click statistics, check Kappa (McNemar also is an option).

If enter data as contingency table (e.g. one column called “count”)
Data $\rightarrow$ Weight cases by count
Ch 9: Models for Correlated, Clustered Responses

Usual models apply (e.g., logistic regr. for binary var., cumulative logit for ordinal) but model fitting must account for dependence (e.g., from repeated measures on subjects).

Generalized Estimating Equation (GEE) approach to repeated measures

• Specify model in usual way.

• Select a “working correlation” matrix for best guess about correlation pattern between pairs of observations.

Ex. For $T$ repeated responses, exchangeable correlation is

\[
\begin{array}{cccccc}
\text{Time} \\
1 & 2 & \cdots & T \\
1 & 1 & \rho & \cdots & \rho \\
\text{Time} & 2 & \rho & 1 & \cdots & \rho \\
\vdots \\
T & \rho & \rho & \cdots & 1
\end{array}
\]

• Fitting method gives estimates that are good even if misspecify correlation structure.
• Fitting method uses empirical dependence to adjust standard errors to reflect actual observed dependence.

• Available in SAS (PROC GENMOD) using REPEATED statement, identifying by
  
  \[ \text{SUBJECT} = \text{var} \]

  the variable name identifying sampling units on which repeated measurements occur.

• In SPSS, Analyze → generalized linear models → generalized estimating equations
  Menu to identify subject variable, working correlation matrix

  **Ex.** Crossover study

<table>
<thead>
<tr>
<th></th>
<th>Placebo</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>S</td>
<td>S</td>
<td>12</td>
</tr>
<tr>
<td></td>
<td>F</td>
<td>49</td>
</tr>
<tr>
<td>F</td>
<td></td>
<td>10</td>
</tr>
<tr>
<td></td>
<td></td>
<td>15</td>
</tr>
<tr>
<td></td>
<td></td>
<td>25</td>
</tr>
<tr>
<td></td>
<td></td>
<td>22</td>
</tr>
<tr>
<td></td>
<td></td>
<td>64</td>
</tr>
<tr>
<td></td>
<td></td>
<td>86</td>
</tr>
</tbody>
</table>

Model

\[
\logit[P(Y_t = 1)] = \alpha + \beta t, \quad t = 1, \text{ drug}, \quad t = 0, \text{ placebo}
\]

GEE fit

\[
\logit[\hat{P}(Y_t = 1)] = -1.07 + 1.96t
\]
Estimated odds of $S$ with drug equal $e^{1.96} = 7.1$ times estimated odds with placebo. 95% CI for odds ratio (for marginal probabilities) is

$$e^{1.96 \pm 1.96(0.377)} = (3.4, 14.9)$$

**Note**

- Sample marginal odds ratio

$$= \frac{61 \times 64}{25 \times 22} = 7.1 \quad (\log \hat{\theta} = 1.96)$$

(model is saturated)

<table>
<thead>
<tr>
<th></th>
<th>S</th>
<th>F</th>
</tr>
</thead>
<tbody>
<tr>
<td>D</td>
<td>61</td>
<td>25</td>
</tr>
<tr>
<td>P</td>
<td>22</td>
<td>64</td>
</tr>
</tbody>
</table>

- With GEE approach, can have also “between-subject” explanatory var’s, such as gender, order of treatments, etc.

- With identity link,

$$\hat{P}(Y_t = 1) = 0.26 + 0.45t$$

i.e., $0.26 = \frac{22}{86} = \text{estimated prob. of success for placebo.}$

$0.26 + 0.45 = 0.71 = \frac{61}{86} = \text{est. prob. of success for drug.}$

$$\hat{\beta} = 0.45 = 0.71 - 0.26 = \text{estimated difference of proportions.}$$
95% CI: $0.45 \pm 1.96(0.075) = (0.307, 0.600)$ for true diff.

**Note**
GEE is a “quasi-likelihood” method

- Assumes dist. (e.g. binomial) for $Y_1$, for $Y_2$, $\cdots$, for $Y_T$, (marginal dist.'s)

- No dist. assumed for joint dist. of $(Y_1, Y_2, \cdots, Y_T)$.

- No likelihood function

No LR inference (LR test, LR CI)

- For responses $(Y_1, Y_2, \cdots, Y_T)$ at $T$ times, we consider marginal model that describes each $Y_t$ in terms of explanatory var’s.

- Alternative conditional model puts terms in model for subjects, effects apply conditional on subject. e.g.

$$\text{logit}[P(Y_{it} = 1) = \alpha_i + \beta t]$$

$\{\alpha_i\}$ (effect for subject $i$) commonly treated as “random effects” having a normal dist. (Ch 10)
Ex \( y \) = response on mental depression (1= normal, 0= abnormal)
three times (1, 2, 4 weeks)
two drug treatments (standard, new)
two severity of initial diagnosis groups (mild, severe)

Is the rate of improvement better with the new drug?

The data are a \( 2 \times 2 \times 2 = 2^3 \) table for profile of responses on \((Y_1, Y_2, Y_3)\) at each of 4 combinations of drug and diagnosis severity.

<table>

</tr>
<tr>
<td>Severe</td>
<td>Standard</td>
<td>0.21</td>
</tr>
<tr>
<td></td>
<td>New</td>
<td>0.18</td>
</tr>
</tbody>
</table>

e.g., 0.51 = \((16+13+9+3)/(16+13+9+3+14+4+15+6)\)
Let $Y_t =$ response of randomly selected subject at time $t$, 
($1 = \text{normal}, \; 0 = \text{abnormal}$)

$s = \text{severity of initial diagnosis} \; (1 = \text{severe}, \; 0 = \text{mild})$

d = \text{drug treatment} \; (1 = \text{new}, \; 0 = \text{standard})$

t = \text{time} \; (0, \; 1, \; 2), \; \text{which is log}_2(\text{week number}).$

Model

$$
\log \left[ \frac{P(Y_t = 1)}{P(Y_t = 0)} \right] = \alpha + \beta_1 s + \beta_2 d + \beta_3 t
$$

assumes same rate of change $\beta_3$ over time for each $(s, d)$ combination.

Unrealistic?
More realistic model

\[
\log \left[ \frac{P(Y_t = 1)}{P(Y_t = 0)} \right] = \alpha + \beta_1 s + \beta_2 d + \beta_3 t + \beta_4 (d \times t)
\]

permits time effect to differ by drug

\(d = 0\) (standard), time effect = \(\beta_3\) for standard drug,

\(d = 1\) (new) time effect = \(\beta_3 + \beta_4\) for new drug.

<table>
<thead>
<tr>
<th>GEE estimates</th>
</tr>
</thead>
<tbody>
<tr>
<td>(\hat{\beta}_1) = -1.31 (s)</td>
</tr>
<tr>
<td>(\hat{\beta}_2) = -0.06 (d)</td>
</tr>
<tr>
<td>(\hat{\beta}_3) = 0.48 (t)</td>
</tr>
<tr>
<td>(\hat{\beta}_4) = 1.02 (d \times t)</td>
</tr>
</tbody>
</table>

Test of \(H_0\): no interaction (\(\beta_4 = 0\)) has

\[
z = \frac{\hat{\beta}_4}{SE} = \frac{1.02}{0.188} = 5.4
\]

Wald stat. \(z^2 = 29.0\) (P<0.0001)

Very strong evidence of faster improvement for new drug.

Could also add \(s \times d\), \(s \times t\) interactions, but they are not significant.
- When diagnosis = severe, estimated odds of normal response are $e^{-1.31} = 0.27$ times estimated odds when diagnosis = mild, at each $d \times t$ combination.

- $\hat{\beta}_2 = -0.06$ is drug effect only at $t = 0$, $e^{-0.06} = 0.94 \approx 1.0$, so essentially no drug effect at $t = 0$ (after 1 week). Drug effect at end of study ($t = 2$) estimated to be $e^{\hat{\beta}_2 + 2(\hat{\beta}_4)} = 7.2$.

- Estimated time effects are
  
  $\hat{\beta}_3 = 0.48$, standard treatment ($d = 0$)
  
  $\hat{\beta}_3 + \hat{\beta}_3 = 1.50$, new treatment ($d = 1$)
Cumulative Logit Modeling of Repeated Ordinal Responses

For multicategory responses, recall popular logit models use logits of cumulative probabilities (ordinal response)

\[
\log\left[ \frac{P(Y \leq j)}{P(Y > j)} \right] \quad \text{cumulative logits}
\]

or logits comparing each probability to a baseline (nominal response)

\[
\log\left[ \frac{P(Y = j)}{P(Y = I)} \right] \quad \text{baseline-category logits}
\]

GEE for cumulative logit models presented by Lipsitz et al. (1994)

SAS (PROC GENMOD) provides with independence working correlations
Ex. Data from randomized, double-blind clinical trial comparing hypnotic drug with placebo in patients with insomnia problems

| Intercept3     | 0.3517   | 0.1784 | 0.0020  | 0.7014  | 1.97   | 0.0487|
| treat          | 0.0336   | 0.2384 | -0.4337 | 0.5009  | 0.14   | 0.8879|
| occasion       | 1.0381   | 0.1676 | 0.7096  | 1.3665  | 6.19   | <.0001|
| treat*occasion | 0.7078   | 0.2435 | 0.2305  | 1.1850  | 2.91   | 0.0037|
\[ Y_t = \text{time to fall asleep} \]
\[ x = \text{treatment} (0 = \text{placebo}, 1 = \text{active}) \]
\[ t = \text{occasion} (0 = \text{initial}, 1 = \text{follow-up after 2 weeks}) \]

**Model**

\[
\text{logit}[P(Y_t \leq j)] = \alpha_j + \beta_1 t + \beta_2 x + \beta_3 (t \times x), \quad j = 1, 2, 3
\]

**GEE estimates:**
\[ \hat{\beta}_1 = 1.04 \ (SE = 0.17), \text{placebo occasion effect} \]
\[ \hat{\beta}_2 = 0.03 \ (SE = 0.24), \text{treatment effect initially} \]
\[ \hat{\beta}_3 = 0.71 \ (SE = 0.24), \text{interaction} \]

Considerable evidence that distribution of time to fall asleep decreased more for treatment than placebo group.

\[ H_0 : \beta_3 = 0 \text{ has } z = \frac{\hat{\beta}_3}{SE} = \frac{0.71}{0.24} = 2.9, \quad P = 0.004 \]

The treatment effect is \( \hat{\beta}_2 = 0.03 \) at \( t = 0 \)
\[ \hat{\beta}_2 + \hat{\beta}_3 = 0.03 + 0.71 = 0.74 \text{ at } t = 1 \]

For the active group, the odds of response \( \leq j \) (e.g. falling asleep in \( \leq 60 \) minutes) are estimated to be

- \( e^{0.03} = 1.03 \) times the odds for placebo, at initial time \( (t = 0) \)
- $e^{0.74} = 2.1$ times the odds for placebo, at follow-up time ($t = 1$)
Handling repeated measurement and other forms of clustered data

Observations \((Y_1, Y_2, \cdots, Y_T)\) (e.g., \(T\) times)

1. **Marginal models** (Ch. 9)

   Simultaneously model each \(E(Y_t)\) \(t = 1, \cdots, T\) get standard errors that account for the actual dependence using method such as GEE (generalized estimating equations)

   e.g. REPEATED statement in PROC GENMOD (SAS)

   **Ex.** binary data \(Y_t = 0\) or 1, \(t = 1, 2\) (matched pair)

   \[ E(Y_t) = P(Y_t = 1) \]

   Model \(\text{logit}[P(Y_t = 1)] = \alpha + \beta x_t\), \(x_t\) is the value of explan. var. for observ. \(t\)

   depression data (matched triplets) \(\rightarrow\) (some explan. var.’s constant across \(t\), others vary)

   **Note:** In practice, missing data is a common problem in longitudinal studies. (no problem for software, but are observations “missing at random”?)
2. **Random effects models** (Ch. 10)

Account for having multiple responses per subject (or “cluster”) by putting a subject term in model

**Ex.** binary data $Y_t = 0$ or $1$

Now let $Y_{it} =$ response by subject $i$ at time $t$

Model

$$\text{logit}[P(Y_{it} = 1)] = \alpha_i + \beta x_t$$

intercept $\alpha_i$ varies by subject

Large positive $\alpha_i$

large $P(Y_{it} = 1)$ each $t$

Large negative $\alpha_i$

small $P(Y_{it} = 1)$ each $t$

These will induce dependence, averaging over subjects.

Heterogeneous popul. $\Rightarrow$ highly variable $\{\alpha_i\}$

**but** number of parameters $>$ number of subjects

**Solution •** Treat $\{\alpha_i\}$ as random rather than parameters (fixed)
• Assume dist. for \( \{ \alpha_i \} \). e.g. \( \{ \alpha_i \} \sim N(\alpha, \sigma) \) (2 para.) or \( \alpha_i = \alpha + u_i \) where is \( \alpha \) a parameter random effects \( \rightarrow \{ u_i \} \sim N(0, \sigma) \)

Model

\[
\text{logit}[P(Y_{it} = 1)] = u_i + \alpha + \beta x_t
\]

\( \{ u_i \} \) are random effects. Parameters such as \( \beta \) are fixed effects.

A generalized linear mixed model (GLMM) is a GLM with both fixed and random effects.

SAS: PROC NLMIXED (ML), PROC GLIMMIX (not ML)

Software must “integrate out” the random effects to get the likelihood fn., ML est. \( \hat{\beta} \) and std. error.

Also estimate \( \sigma \) and can predict \( \{ u_i \} \).

Ex. depression study

We used GEE to fit “marginal model”

\[
\text{logit}[P(Y_t = 1)] = \alpha + \beta_1 s + \beta_2 d + \beta_3 t + \beta_4 (d \times t)
\]

\(Y_t = 1\) (normal), \(s\) : severity (=1 severe), \(d\) : drug (=1 new), \(t\) : time (= 0,1,2).

Now we use ML to fit “random effects” model

\[
\text{logit}[P(Y_{it} = 1)] = u_i + \alpha + \beta_1 s + \beta_2 d + \beta_3 t + \beta_4 (d \times t)
\]

assume \(\{u_i\}\) has \(N(0, \sigma)\) (need to estimate \(\sigma\)).

\[\hat{\beta}_1 = -1.32\] severity effect

\[\hat{\beta}_2 = -0.06\] drug effect at \(t = 0\)
$\hat{\beta}_3 = 0.48$  time effect for standard drug ($d = 0$)

$\hat{\beta}_4 = 1.02$  add to $\hat{\beta}_3$ to get time effect for new drug ($d = 1$)

$\hat{\sigma} = 0.07$  est. std. dev. of random effects

Note

- Similar conclusions as with marginal model (e.g., significant interaction)

- When $\hat{\sigma} = 0$, estimates and std. errors same as treating repeated observ’s as independent

- Details: Ch.10 of textbook

- When $\hat{\sigma}$ is large, estimates from random effects logit model tend to be larger than estimates from marginal logit model.

Graph here
Ch 7: Loglinear Models

- Logistic regression distinguishes between response variable $Y$ and explanatory variables $x_1, x_2, \ldots$.

- Loglinear models treat all variables as response variables (like correlation analysis).

Ex. (text) Survey of high school students

$Y_1$: used marijuana? (yes, no)

$Y_2$: alcohol? (yes, no)

$Y_3$: cigarettes? (yes, no)

Any variables independent?
Strength of association?
Interaction?
Loglinear models treat cell counts as Poisson and use the log link function.

Motivation: In $I \times J$ table, $X$ and $Y$ are independent if

$$P(X = i, Y = j) = P(X = i)P(Y = j) \text{ for all } i, j.$$  

$$\pi_{ij} = \pi_{i+} \pi_{+j}$$

For expected frequencies

$$\mu_{ij} = n \pi_{ij}$$

$$\mu_{ij} = n \pi_{i+} \pi_{+j}$$

$$\log(\mu_{ij}) = \lambda + \lambda_i^X + \lambda_j^Y$$

$\lambda_i^X$: effect of $X$ falling in row $i$

$\lambda_j^Y$: effect of $Y$ falling in column $j$

This is loglinear model of independence

Treats $X$ and $Y$ symmetrically

(differs from logistic regression, which distinguishes between $Y =$response and $X =$explanatory)
Ex. Income and job satisfaction

<table>
<thead>
<tr>
<th>Income ($1000)</th>
<th>Job Satisfaction (Y)</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Very dissat.</td>
</tr>
<tr>
<td>&lt; 5</td>
<td>2</td>
</tr>
<tr>
<td>5 – 15</td>
<td>2</td>
</tr>
<tr>
<td>15 – 25</td>
<td>0</td>
</tr>
<tr>
<td>&gt; 25</td>
<td>0</td>
</tr>
</tbody>
</table>

Using $x =$income scores $(3, 10, 20, 30)$, we used SAS (PROC LOGISTIC) to fit model

$$\log \left( \frac{\pi_i}{\pi_4} \right) = \alpha_j + \beta_j x, \quad j = 1, 2, 3$$
Income (I) and job satisfaction (S)

(We analyzed this using multinominal logit models in Ch. 6)

Model
\[ \log(\mu_{ij}) = \lambda + \lambda^I_i + \lambda^S_j \]
can be expressed as
\[ \log(\mu_{ij}) = \lambda + \lambda^I_1 z_1 + \lambda^I_2 z_2 + \lambda^I_3 z_3 + \lambda^S_1 w_1 + \lambda^S_2 w_2 + \lambda^S_3 w_3 \]
where
\[ z_1 = 1, \text{ income cat. 1 } \]
\[ 0, \text{ otherwise } \]
\[ \ldots \]
\[ z_3 = 1, \text{ income cat. 3 } \]
\[ 0, \text{ otherwise } \]
\[ \ldots \]
\[ w_1 = 1, \text{ sat. cat. 1 } \]
\[ 0, \text{ otherwise } \]
\[ \ldots \]
\[ w_3 = 1, \text{ sat. cat. 3 } \]
\[ 0, \text{ otherwise } \]
<table>
<thead>
<tr>
<th>Parameter</th>
<th>No. nonredundant</th>
</tr>
</thead>
<tbody>
<tr>
<td>$\lambda$</td>
<td>1 (can set $\lambda^X_I = 0$)</td>
</tr>
<tr>
<td>$\lambda^X_i$</td>
<td>$I - 1$</td>
</tr>
<tr>
<td>$\lambda^Y_j$</td>
<td>$J - 1$ (can set $\lambda^Y_J = 0$)</td>
</tr>
<tr>
<td>$\lambda^{XY}_{ij}$</td>
<td>$(I - 1)(J - 1)$ (no. of products of dummy var’s)</td>
</tr>
</tbody>
</table>

**Note.**

For a Poisson loglinear model

$$df = \text{no. Poisson counts} - \text{no. parameters}$$

(no. Poisson counts = no. cells)

**Ex.** Independence model, $I \times J$ table

$$\log \mu_{ij} = \lambda + \lambda^X_i + \lambda^Y_j$$

$$df = IJ - [1 + (I - 1) + (J - 1)] = (I - 1)(J - 1)$$

Test of indep. using Pearson $X^2$ or like-ratio $G^2$ is a goodness-of-fit test of the indep. loglinear model.

The model allowing association

$$\log \mu_{ij} = \lambda + \lambda^X_i + \lambda^Y_j + \lambda^{XY}_{ij}$$

has df= 0 (saturated), giving a perfect fit.
Ex. Recall $4 \times 4$ table

Independence model

$$\log(\mu_{ij}) = \lambda + \lambda^I_i + \lambda^S_j$$

has $X^2 = 11.5$, $G^2 = 13.5$, df = 9.

Saturated model: $X^2 = G^2 = 0$, df = 0. (All $\hat{\mu}_{ij} = n_{ij}$)
Estimated odds ratio using highest and lowest categories is

\[
\frac{\hat{\mu}_{11} \hat{\mu}_{44}}{\hat{\mu}_{14} \hat{\mu}_{41}} = \exp \left[ \lambda_{11}^{IS} + \lambda_{44}^{IS} - \lambda_{14}^{IS} - \lambda_{41}^{IS} \right]
\]

\[
= \exp(24.288) = 35,294,747,720 \quad \text{(GENMOD)}
\]

\[
= \frac{n_{11} n_{44}}{n_{14} n_{41}} = \frac{2 \times 8}{3 \times 0} = \infty
\]

since model is saturated

(software doesn’t quite get right answer when ML est. = \infty)
Loglinear Models for Three-way Tables

Two-factor terms represent conditional log odds ratios, at fixed level of third var.

Ex. $2 \times 2 \times 2$ table

Let $\mu_{ijk}$ denotes expected freq.; $\lambda_{ik}^X$ and $\lambda_{jk}^Z$ denote assoc. para.’s.

$$\log \mu_{ijk} = \lambda + \lambda_i^X + \lambda_j^Y + \lambda_k^Z + \lambda_{ik}^XZ + \lambda_{jk}^YZ$$

satisfies

- $\log \theta_{XY(Z)} = 0$ ($X$ and $Y$ cond. indep., given $Z$)
- $\log \theta_{X(j)Z} = \lambda_{11}^{XZ} + \lambda_{22}^{XZ} - \lambda_{12}^{XZ} - \lambda_{21}^{XZ} = 0$ if $\{\lambda_{ij}^{XZ} = 0\}$

i.e. the $XZ$ odds ratio is same at all levels of $Y$

Denote by $(XZ, YZ)$, called model of $XY$ conditional independence.

Ex.

$$\log \mu_{ijk} = \lambda + \lambda_i^X + \lambda_j^Y + \lambda_k^Z + \lambda_{ij}^{XY} + \lambda_{ik}^{XZ} + \lambda_{jk}^{YZ}$$
called model of homogeneous association

Each pair of var’s has association that is identical at all levels of third var.

Denote by $(XY, XZ, YZ)$.
Ex. Berkeley admissions data \((2 \times 2 \times 6)\)
Gender(M,F) \(\times\) Admitted(Y, N) \(\times\) Department(1,2,3,4,5,6)

Recall marginal \(2 \times 2\) AG table has \(\hat{\theta} = 1.84\)

- Model (AD, DG)

A and G cond. indep., given D.

\[\text{e.g. for Dept. 1,}\]
\[
\hat{\theta}_{AG(1)} = \frac{531.4 \times 38.4}{293.6 \times 69.6} = 1.0
\]
\[
= \hat{\theta}_{AG(2)} = \ldots = \hat{\theta}_{AG(6)}
\]

But model fits poorly: \(G^2 = 21.7, X^2 = 19.9, df = 6\)
\((P < .0001)\) for \(H_0:\) model (AD, DG) holds.

Conclude A and G \underline{not} cond. indep given D.
• Model \((AG, AD, DG)\)

Also permits AG assoc., with same odds ratio for each dept.

e.g. for Dept. 1,

\[
\hat{\theta}_{AG(1)} = \frac{529.3 \times 36.3}{295.7 \times 71.7} = 0.90 \\
= \hat{\theta}_{AG(2)} = \ldots = \hat{\theta}_{AG(6)} \\
= \exp(\lambda_{11}^{AG} + \lambda_{22}^{AG} - \lambda_{12}^{AG} - \lambda_{21}^{AG}) \\
= \exp(-0.999) = 0.90
\]

Control for dept., estimated odds of admission for males equal \(0.90\) times est. odds for females.

\(\hat{\theta} = 1.84\) ignores dept. (Simpson’s paradox)

But this model also fits poorly: \(G^2 = 20.2, X^2 = 18.8, df = 5\) \((P < .0001)\) for \(H_0: \) model (AG, AD, DG) holds.

i.e. true AG odds ratio not identical for each dept.

• Adding 3-factor interaction term \(\lambda_{ijk}^{GAD}\) gives saturated model \((1 \times 1 \times 5\) cross products of dummies)
Residual analysis

For model (AD, DG) or (AD, AG, DG), only Dept. 1 has large adjusted residuals. (≈ 4 in abs. value)

Dept. 1 has

- fewer males accepted than expected by model
- more females accepted than expected by model

If re-fit model (AD, DG) to $2 \times 2 \times 5$ table for Depts 2-6, $G^2 = 2.7$, $df = 5$, good fit.

Inference about Conditional Associations

EX. Model (AD, AG, DG)

$$\log \mu_{ijk} = \lambda + \lambda_i^G + \lambda_j^A + \lambda_k^D + \lambda_{ij}^{GA} + \lambda_{ik}^{GD} + \lambda_{jk}^{AD}$$

$H_0 : \lambda_{ij}^{GA} = 0$ (A cond. indep of G, given D)

Likelihood-ratio stat. $-2(L_0 - L_1)$

= deviance for (AD, DG) -deviance for (AD, AG, DG)

= 21.7 - 20.3 = 1.5, with df=6-5=1 ($P = .21$)

$H_0$ plausible, but test “shaky” because model (AD, AG, DG) fits poorly.
Recall $\hat{\theta}_{AG(D)} = \exp \left( \hat{\lambda}^{AG}_{11} \right) = \exp(-.0999) = .90$

95\% CI for $\theta_{AG(D)}$ is

$$\exp[-.0999 \pm 1.96(.0808)] = (.77, 1.06)$$

Plausible that $\theta_{AG(D)} = 1$.

There are equivalences between loglinear models and corresponding logit models that treat one of the variables as a response var., others as explanatory. (Sec. 6.5)

**Note.**

- Loglinear models extend to any no. of dimensions
- Loglinear models treat all variables symmetrically; Logistic regr. models treat $Y$ as response and other var’s as explanatory.
  Logistic regr. is the more natural approach when one has a single response var. (e.g. grad admissions) See output for logit analysis of data
Ex Text Sec. 6.4, 6.5

Auto accidents

\( G = \) gender (F, M)

\( L = \) location (urban, rural)

\( S = \) seat belt use (no, yes)

\( I = \) injury (no, yes)

\( I \) is natural response var.

Loglinear model (GLS, IG, IL, IS) fits quite well (\( G^2 = 7.5, df = 4 \))

Simpler to consider logit model with \( I \) as response.

\[ \text{logit} \left[ \hat{P}(I = \text{yes}) \right] = -3.34 + 0.54G + 0.76L + 0.82S \]

Controlling for other variables, estimated odds of injury are:

\[ e^{0.54} = 1.72 \text{ times higher for females than males (CI: (1.63, 1.82))} \]
\[ e^{0.76} = 2.13 \text{ times higher in rural than urban locations} \quad (\text{CI: (2.02, 2.25)}) \]

\[ e^{0.82} = 2.26 \text{ times higher when not wearing seat belt} \quad (\text{CI: (2.14, 2.39)}) \]

Why ever use loglinear model for contingency table?

Info. about all associations, not merely effects of explanatory var’s on response.

\textbf{Ex.} Auto accident data

Loglinear model (GI, GL, GS, IL, IS, LS) \((G^2 = 23.4, df = 5)\) fits almost as well as (GLS, GI, IL, IS) \((G^2 = 7.5, df = 4)\) in practical terms but \(n\) is huge (68,694)

<table>
<thead>
<tr>
<th>Variables</th>

</tbody>
</table>

\(\text{e.g., for those not wearing seat belts, the estimated odds of being in-}\)
jured are 2.26 times the estimated odds of injury for those wearing seat belts, cont. for gender and location. (or. interchanges $S$ and $I$ in interp.)

Dissimilarity index

$$D = \sum |p_i - \hat{\pi}_i|/2$$

- $0 \leq D \leq 1$, with smaller values for better fit.

- $D = $ proportion of sample cases that must move to different cells for model to fit perfectly.

*Ex.* Loglinear model (GLS, IG, IL, IS) has $D = 0.003$.

Simpler model (GL, GS, LS, IG, IL, IS) has $G^2 = 23.4$ (df=5) for testing fit ($P<0.001$), but $D = 0.008$. (Good fit for practical purposes, and simpler to interpret GS,LS associations.)

For large $n$, effects can be “statistically significant” without being “practically significant.”

Model can fail goodness-of-fit test but still be adequate for practical purposes.
Can be useful to describe closeness of sample cell proportions \( \{ p_i \} \) in a contingency table to the model fitted proportions \( \{ \hat{\pi}_i \} \).
